Abstract

Hot stage in transmission electron microscope has been used to study the structure and stability of Nd-rich phase in NdFeB magnet. The present observation shows that the so-called complex cubic phase is in fact the prototype of Mn\textsubscript{2}O\textsubscript{3} (space group I\textsuperscript{a\textsubscript{3}}\textsuperscript{/}C\textsuperscript{2\textsubscript{2}}\textsuperscript{3}) with lattice parameter of \(a = 1.08\) nm. The Nd-rich phase with P\textsuperscript{3\textsubscript{1}}m\textsubscript{1} structure (h-Nd\textsubscript{2}O\textsubscript{3}) was first observed to be transformed from the BCC phase after in situ heating over 400°C. The orientation relationship between these two structures satisfies as follows: (0 0 0 1)\textsubscript{HCP}//(2 0 0)\textsubscript{BCC}, \(\{\overline{1}0\overline{1}\}\text{HCP} = \{020\}\text{BCC}\); \(\{\overline{1}2\overline{1}\}\text{HCP} = \{001\}\text{BCC}\). It is argued that the h-Nd\textsubscript{2}O\textsubscript{3} was arising from the oxidation of the BCC Nd-rich phase rather than from Nd\textsubscript{2}Fe\textsubscript{14}B matrix phase as suggested in the literature.

1. Introduction

The NdFeB magnet normally contains three phases: Nd\textsubscript{2}Fe\textsubscript{14}B matrix, a small volume fraction of NdFe\textsubscript{4}B\textsubscript{4} phase and Nd-rich phase at grain boundaries [1,2]. Considerable effort has been expended in study of Nd-rich phase since the grain boundary phases are believed to have a strong influence on the coercivity of the magnets.

From the literature, it appears that the Nd-rich regions are rather complex. Four kinds of structures have been reported as shown in Table 1. Fidler [3] observed an Nd-rich phase having a double hexagonal structure (so-called DHCP-Nd\textsubscript{2}O\textsubscript{3}) in sintered magnets. After annealing at 1080°C for 50 min, the DHCP phase would transform to an FCC NdO phase (NaCl prototype) [4] at \(O > 0.57\) at% [5]. Under electron irradiation, the...
fundamental FCC patterns of NdO phase were superimposed by weak reflections. Lemarchand et al. [5] and Yin et al. [6] attributed them to a BCC Nd2O3 coexistence with an FCC NdO. However, TEM dark field did not favour two phases coexisting, and a BCC superlattice with twice the lattice parameter of the fundamental FCC lattice was suggested [7]. The fourth structure of Nd-rich phases is a HCP structure with the lattice parameters $a = 0.383nm$ and $c = 0.600nm$ [8], which was proposed arising from the decomposition of matrix phase ($Nd_2Fe_{14}B$) due to the oxidation at high temperatures based on X-ray diffraction (XRD) [9]:

$$Nd_2Fe_{14}B + 3/2O_2 \rightarrow h-Nd_2O_3 + 14Fe + B.$$  

(1)

This reaction was supported by the recent TEM work on selected area electron diffraction pattern [10]. In contrast, Li et al. [11] found that the product of Nd-rich phase from matrix phase ($Nd_2Fe_{14}B$) was amorphous on high-resolution electron microscopy (HREM).

The purpose of this paper is to clarify the origin of h-Nd2O3. Hot stage in TEM was used and the relationship between two Nd-rich structures was first observed.

2. Experimental procedure

The NdFeB magnets used for this study were supplied by Philips Component Ltd. and had a nominal composition of $Nd_{15}Fe_{76.5}B_{7.0}Dy_{0.4}Nb_{0.5}Al_{0.6}$ (at%). The magnets were produced by a powder metallurgy method (ingot→HD→jet milling→powder alignment→pressing→sintering) and were finally demagnetised. The magnets were stuck on a glass slide using a low melting point wax and cut into small pieces about 16 mm in width using a low-speed diamond saw. The pieces were ground on 1200-grid SiC papers to around 80 nm thickness and then glued on a 1/2 mm slot copper grid. The grid was single-side dimpled using 6 µm diamond paste in a South Bay Technology Model 515 dimpler until the thickness at the centre was about 40 µm. Finally, they were ion milled by Gatan DuoMill model 600 using 6 kV voltage and 6–12 $^\circ$ Ar ion beam incidence angle until perforation. TEM observations were carried out in a JEOL 4000FX at both room temperature and in situ heating.

3. Results and discusions

3.1. Nd-rich phase

The microstructure of a sintered magnet consists of matrix grains of approximately 3–7 µm diameter. Fig. 1 shows a triangular region of an Nd-rich phase among Nd2Fe14B grains. Energy dispersive spectrometer microanalysis indicated the Nd-rich region had 50 ± 10 at% oxygen. Fig. 2(a) shows a series of selected area electron diffraction (SAD) patterns tilted from the decomposed matrix phase ($Nd_2Fe_{14}B$) due to the oxidation at high temperatures based on X-ray diffraction (XRD) [9]:

to be [0 0 1], [0 1 1] and [1 1 1], respectively. The simulated diagrams shown in Fig. 2(b), based on coordinates of $\beta$-Mn$_2$O$_3$ type, correspond well with the real diffraction patterns of Fig. 2(a).

In order to study the stability of the BCC phase, hot stage TEM was performed. Firstly the Nd-rich phase was tilted to [0 0 1] axis (Fig. 3a) at room temperature then was in situ heated in the microscope. It was observed that BCC-Nd$_2$O$_3$ was stable up to 300 °C and started to become unstable at 350 °C, and finally transformed to HCP (La$_2$O$_3$ prototype) at 400 °C. The orientation relationship between these two structures was determined as following: (0 0 1)$_{\text{HCP}}$//(2 0 0)$_{\text{BCC}}$, (1 0 1)$_{\text{HCP}}$//(0 2 0)$_{\text{BCC}}$, [1 2 10]$_{\text{HCP}}$//[0 0 1]$_{\text{BCC}}$.

3.2. Nd$_2$Fe$_{14}$B phase

The matrix Nd$_2$Fe$_{14}$B phase was also observed to decompose during the in situ heating. Fig. 4(a) shows [1 2 1]$_{\text{Nd$_2$Fe$_{14}$B}}$ zone of as-received sample. After continuous heating inside the microscopy, diffraction rings of polycrystalline $\alpha$-Fe appear to superimpose on the diffraction pattern of the Nd$_2$Fe$_{14}$B phase after 300 °C as shown in Fig. 4(b). At 400 °C the diffraction spots of the Nd$_2$Fe$_{14}$B phase completely disappear, as shown in Fig. 4(c). To study the origin of diffraction rings, the theoretical spacings of $\alpha$-Fe (Table 2) have been ringed to compare the observed diffraction rings (Fig. 4c). As shown in Fig. 5, the spacings of $\alpha$-Fe crystallines, designated by solid lines, match all the observed diffraction

rings, except a broad diffraction ring with a mean spacing of \( d = 0.3 \text{ nm} \) (designated as I in Fig. 5). Furthermore, the diffraction intensities of \( \alpha \)-Fe, shown in Table 2, are consistent to the intensities of the observed diffractions (as shown in Fig. 5). The broad ring of the spacing of 0.3 nm, which cannot be explained by the structure of \( \alpha \)-Fe, was attributed to \( h \)-Nd\(_2\)O\(_3\) by Zhu et al. [10]. However, most of spacings of \( h \)-Nd\(_2\)O\(_3\), as drawn by dashed semi-cycles in Fig. 5 do not match the actual diffraction rings. Interestingly, the SAD on amorphous Nd-rich phase [12] showed a diffuse ring of the same spacing (0.3 nm). Therefore, the diffuse ring I in Fig. 5 is more appropriate from the amorphous regions rather than from the crystallines of \( h \)-Nd\(_2\)O\(_3\). This argument has been further supported by HREM. Fig. 6 shows a high-resolution micrograph from a sample after oxidation at 400 °C for 2 days. The spacing of 0.20 nm, which corresponding to 1 1 0 planes of \( \alpha \)-Fe, can be dissolved clearly. And amorphous regions around 2 nm in diameter...

(some regions are circled) are dispersed among these $\alpha$-Fe crystallines.

4. Conclusions

The present observation shows that complex-Nd$_2$O$_3$ has the prototype of Mn$_2$O$_3$ (space group Ia$\overline{3}$) with lattice parameter of $a = 1.08\text{nm}$. The BCC phase will further oxidise to P$\overline{3}$m1 structure (prototype of La$_2$O$_3$). Diffraction and HREM support the argument that h-Nd$_2$O$_3$ forms from complex-Nd$_2$O$_3$ rather than from the decomposition of the Nd$_2$Fe$_{14}$B matrix.

Acknowledgment

The paper is part of Ph.D. work (Y. Li) and Y. Li would like to thank professors I.R. Harris and I.P. Jones of Birmingham University, UK and Professor M. Aindow of University of Connecticut, USA for the Ph.D. supervision. Financial support was provided by the committee of Vice Chancellors and Principals under the Oversea Research Scholar (ORS) Scheme, School of Metallurgy and Materials, The University of Birmingham and School of Engineering Science, The University of Southampton.
