Abstract

In recent years backtrack search SAT solvers have been the subject of dramatic improvements. These improvements allowed SAT solvers to successfully replace BDDs in many areas of formal verification, and also motivated the development of many new challenging problem instances, many of which too hard for the current generation of SAT solvers. As a result, further improvements to SAT technology are expected to have key consequences in formal verification. The objective of this paper is to propose heuristic approaches to the backtrack step of backtrack search SAT solvers, with the goal of increasing the ability of the SAT solver to search different parts of the search space. The proposed heuristics to the backtrack step are inspired by the heuristics proposed in recent years for the branching step of SAT solvers, namely VSIDS and some of its improvements. The preliminary experimental results are promising, and motivate the integration of heuristic backtracking in state-of-the-art SAT solvers.

1. Introduction

Propositional Satisfiability is a well-known NP-complete problem, with theoretical and practical significance, and with extensive applications in many fields of Computer Science and Engineering, including Artificial Intelligence and Electronic Design Automation.

Current state-of-the-art SAT solvers incorporate sophisticated pruning techniques as well as new strategies on how to organize the search. Effective search pruning techniques are based, among others, on nogood learning and dependency-directed backtracking [15] and backjumping [4], whereas recent effective strategies introduce variations on the organization of backtrack search. Examples of such strategies are weak-commitment search [16], search restarts [8] and random backtracking [9].

Advanced techniques applied to backtrack search SAT algorithms have achieved remarkable improvements [7, 11, 12], having been shown to be crucial for solving hard instances of SAT obtained from real-world applications. Moreover, and from a practical perspective, the most effective algorithms are complete, and so able to prove what local search is not capable of, i.e. unsatisfiability. Indeed, this is often the objective in a large number of significant real-world applications.

Nevertheless, it is also widely accepted that local search [14] can often have clear advantages with respect to backtrack search, since it is allowed to start the search over again whenever it gets *stuck* in a locally optimal partial solution. This advantage of local search has motivated the study of approaches for relaxing backtracking conditions (while still assuring completeness). The key idea is to *unrestrictedly* choose the point to backtrack to, in order to avoid thrashing during backtrack search. Moreover, one can think of combining different forms of relaxing the identification of the backtrack point. In this paper, we propose to use heuristic knowledge to select the backtrack point. The heuristics that we consider are inspired in the most promising branching heuristics proposed in recent years, namely the VSIDS heuristic used by Chaff [12] and Berkmin's branching heuristic [7].

The remainder of this paper is organized as follows. The next section introduces the definitions that will be used throughout the paper. Then we present a brief survey of backtrack search SAT algorithms. Section 4 describes heuristic backtracking and further relates heuristic backtracking with unrestricted backtracking. Afterwards, we relate our work with previous work on the same topic. Finally, we present preliminary experimental results and conclude with directions for future research work.

2. Definitions

This section introduces the notational framework used throughout the paper. Propositional variables are denoted $x_1, \ldots, x_n$, and can be assigned truth values 0 (or F) or 1 (or T). The truth value assigned to a variable x is denoted by $\nu(x)$. (When clear from context we use $x = \nu_x$, where $\nu_x \in \{0, 1\}$). A literal l is either a variable x or its negation $\neg x$. A clause ω is a disjunction of literals and a CNF

formula φ is a conjunction of clauses. A clause is said to be *satisfied* if at least one of its literals assumes value 1, *unsatisfied* if all of its literals assume value 0, *unit* if all but one literal assume value 0, and *unresolved* otherwise. Literals with no assigned truth value are said to be *free literals*. A formula is said to be *satisfied* if all its clauses are satisfied, and is *unsatisfied* if at least one clause is unsatisfied. A *truth assignment* for a formula is a set of assigned variables and their corresponding truth values. The SAT problem consists of deciding whether there exists a truth assignment to the variables such that the formula becomes satisfied.

SAT algorithms can be characterized as being either *complete* or *incomplete*. Complete algorithms can establish unsatisfiability if given enough CPU time; incomplete algorithms cannot. Consequently, incomplete algorithms are only used for satisfiable instances. Examples of complete and incomplete algorithms are backtrack search and local search algorithms, respectively. In a search context, complete algorithms are often referred to as *systematic*, whereas incomplete algorithms are referred to as *non-systematic*.

3. Backtrack Search SAT Algorithms

Over the years a large number of algorithms have been proposed for SAT, from the original Davis-Putnam procedure [3], to recent backtrack search algorithms [7, 11, 12] and to local search algorithms [14], among many others.

The vast majority of backtrack search SAT algorithms build upon the original backtrack search algorithm of Davis, Logemann and Loveland [2]. The backtrack search algorithm is implemented by a *search process* that implicitly enumerates the space of 2^n possible binary assignments to the n problem variables. Each different truth assignment defines a *search path* within the search space. A *decision level* is associated with each variable selection and assignment. The first variable selection corresponds to decision level 1, and the decision level is incremented by 1 for each new decision assignment [1]. In addition, and for each decision level, the *unit clause rule* [3] is applied. If a clause is unit, then the sole free literal must be assigned value 1 for the formula to be satisfied. In this case, the value of the literal and of the associated variable are said to be *implied*. The iterated application of the unit clause rule is often referred to as Boolean Constraint Propagation (BCP).

In chronological backtracking, the search algorithm keeps track of which decision assignments have been toggled. Given an unsatisfied clause (i.e. a *conflict* or a *dead end*) at decision level d, the algorithm checks whether at the current decision level the corresponding decision variable x has already been toggled. If not, the algorithms erases the variable assignments which are implied by the assignment on x, including the assignment on x, assigns the opposite value to x, and marks decision variable x as toggled. In contrast, if the value of x has already been toggled, the search backtracks to decision level $d-1$.

Recent state-of-the-art SAT solvers utilize different forms of non-chronological backtracking [7, 11, 12], in which each identified conflict is analyzed, its causes identified, and a new clause created to explain and prevent the identified conflicting conditions. Created clauses are then used to compute the backtrack point as the *most recent* decision assignment from all the decision assignments represented in the recorded clause. Moreover, some of the (larger) recorded clauses are eventually deleted. Clauses can be deleted opportunistically whenever they are no longer *relevant* for the current search path [11].

4. Heuristic Backtracking

Heuristic backtracking consists of selecting the backtrack point in the search tree as a function of variables in the most recently recorded clause. Different heuristics can be envisioned. In this work we implemented different heuristics:

1. One heuristic that decides the backtrack point given the information of the most recently recorded conflict clause.
2. Another heuristic that is inspired in the VSIDS branching heuristic, used by Chaff [12].
3. Finally, one heuristic that is inspired by Berkmin's branching heuristic [7].

In all cases the backtrack point is computed as the variable with the largest heuristic metric. Completeness is ensured by marking the recorded clause as non-deletable.

We should observe that heuristic backtracking can be viewed as a special case of unrestricted backtracking [9]. While in unrestricted backtracking any form of backtrack step can be applied, in heuristic backtracking the backtrack point is computed from heuristic information, obtained from the current and past conflicts.

Next, we describe how the three different approaches of using heuristics are implemented in the heuristic backtracking algorithm.

4.1. Plain Heuristic Backtracking

Under the plain heuristic backtracking approach the backtrack point (i.e. decision level) is computed by selecting the decision level with the largest number of occur-

1 Observe that all the assignments made before the first decision assignment correspond to decision level 0.

rences in a recorded clause. Afterwards, the search process backtracks to that decision level.

4.2. VSIDS-like Heuristic Backtracking

The second approach to heuristic backtracking is based on the variable state independent decaying sum (VSIDS) branching heuristic of Chaff [12]. As in Chaff, a metric is associated with each literal, which is incremented when a new clause containing the literal is recorded; after every k decisions, the metric values are divided by a small constant. With the VSIDS-like heuristic backtracking, the assigned literal with the highest metric (of the literals in the recorded clause) is selected as the backtrack point.

4.3. BerkMin-like Heuristic Backtracking

The third approach for implementing heuristic backtracking is inspired in BerkMin's branching heuristic [7]. This heuristic is similar to the VSIDS heuristic used in Chaff, but the process of updating the metrics of the literals differs. In Berkmin's heuristic, the metrics of the literals of all clauses that are directly involved in producing the conflict, and so in creating the newly recorded clause, are updated when a clause is recorded. As in the case of the VSIDS-like backtracking heuristic, the assigned literal with the highest metric (of the literals in the recorded clause) is selected as the backtrack point.

4.4. Relation with Unrestricted Backtracking

As mentioned above, heuristic backtracking can be viewed as a special case of unrestricted backtracking [9], the main difference being that while in unrestricted backtracking any form of backtrack step can be applied, in heuristic backtracking the backtrack point is computed from heuristic information, obtained from the current and past conflicts. As with unrestricted backtracking, a number of techniques can be used to ensure completeness. These techniques are analyzed in [9], and can be organized in two classes:

- Marking recorded clauses as non-deletable. This solution may yield an exponential growth in the number of recorded clauses.
- Increasing the number of conflicts in between applications of heuristic backtracking. This solution can be used to guarantee a polynomial growth of the number of recorded clauses.

5. Related Work

Dependency-directed backtracking and nogood learning were originally proposed by Stallman and Sussman in [15] in the area of Truth Maintenance Systems (TMS). In the area of Constraint Satisfaction Problems (CSP), the topic was independently studied by J. Gaschnig [4] as different forms of backjumping.

The introduction of relaxations in the backtrack step is also related with dynamic backtracking [5]. Dynamic backtracking establishes a method by which backtrack points can be moved deeper in the search tree. This allows avoiding the unneeded erasing of the amount of search that has been done thus far. The objective is to find a way to directly "erase" the value assigned to a variable as opposed to backtracking to it, moving the backjump variable to the end of the partial solution in order to replace its value without modifying the values of the variables that currently follow it. More recently, Ginsberg and McAllester combined local search and dynamic backtracking in an algorithm which enables arbitrary search movement [6], starting with *any complete assignment* and evolving by flipping values of variables obtained from the conflicts.

In weak-commitment search [16], the algorithm constructs a consistent partial solution, but commits to the partial solution *weakly*. In weak-commitment search, whenever a conflict is reached, the *whole* partial solution is abandoned, in explicit contrast to standard backtracking algorithms where the most recently added variable is removed from the partial solution.

Moreover, search restarts have been proposed and shown effective for hard instances of SAT [8]. The search is repeatedly restarted whenever a cutoff value is reached. The algorithm proposed is not complete, since the restart cutoff point is kept constant. In [1], search restarts were jointly used with learning for solving hard real-world instances of SAT. This latter algorithm is complete, since the backtrack cutoff value increases after each restart. One additional example of backtracking relaxation is described in [13], which is based on attempting to construct a complete solution, that restarts each time a conflict is identified. More recently, highly-optimized complete SAT solvers [7, 12] have successfully combined non-chronological backtracking and search restarts, again obtaining remarkable improvements in solving real-world instances of SAT.

6. Experimental Results

This section presents the experimental results of applying heuristic backtracking to different classes of problem instances. In addition, we compare heuristic backtracking with other forms of backtracking relaxations, namely search restarts [8] and random backtracking [9] [2]. Our goal here has been to test the feasibility of heuristic backtracking al-

2 With random backtracking, and whenever a conflict is found, the backtrack point is *randomly* selected.

gorithm using three different heuristics: a default heuristic, the VSIDS heuristic and the Berkmin's heuristic.

Experimental evaluation of the different algorithms has been done using the JQUEST SAT framework [10], a Java framework for prototyping SAT algorithms. All the experiments were run on the same P4/1.7GHz/1GByte of RAM/Linux machine. The CPU time limit for each instance was set to 2000 seconds, except for instances from Beijing family, for which the maximum run time allowed was 5000 seconds. In all cases where the algorithm was unable to solve an instance was due to memory exhaustion. The total run time for solving different classes of benchmarks are shown in Table 1 and results for some specific instances are shown in Table 2. In both tables, *Time* denotes the CPU time and *X* denotes the number of aborted instances. In addition, each column indicates a different form of backtracking relaxation:

- RST indicates that the search restart strategy is applied with a cutoff value of 100 backtracks and is kept fixed. All recorded clauses are kept to ensure completeness.
- RB indicates that random backtracking is applied at each backtrack step.
- HB(P) indicates that plain heuristic backtracking is applied at each backtrack step. All recorded clauses are kept.
- HB(C) indicates that the Chaff's VSIDS-like heuristic backtracking is applied at each step. All recorded clauses are kept.
- HB(B) indicates that the Berkmin-like heuristic backtracking is applied at each step. All recorded clauses are kept.

As can be concluded from the experimental results, heuristic backtracking can yield significant savings in CPU time, and also allow for a smaller number of instances to be aborted. This is true for several of the classes of problem instances analyzed.

7. Conclusions and Future Work

This paper proposes the utilization of heuristic backtracking in backtrack search SAT solvers. The most well-known branching heuristics used in state-of-the-art SAT solvers were adapted to the backtrack step of SAT solvers. The experimental results illustrate the practicality of heuristic backtracking.

The main contributions of this paper can be summarized as follows:

1. A new heuristic backtrack search SAT algorithm is proposed, that heuristically selects the point to backtrack to.
2. The proposed SAT algorithm is shown to be a special case of unrestricted backtracking, where different approaches for ensuring completeness can be utilized.
3. Experimental results indicate that significant savings in search effort can be obtained for different organizations of the proposed heuristic backtrack search algorithm.

Besides the preliminary experimental results, a more comprehensive experimental evaluation is required. In addition, future work entails deriving conditions for selecting among search restarts and heuristic backtracking.
