Background: Several cluster-randomized HIV prevention trials aim to demonstrate the population-level preventive impact of antiretroviral therapy (ART). 2013 World Health Organization (WHO) guidelines raising the ART initiation threshold to CD4 <500/µL could attenuate these trials’ effect size by increasing ART usage in control clusters. Methods: We used a computational model to simulate strategies from a hypothetical cluster-randomized HIV prevention trial. The primary model outcome was the relative reduction in 24-month HIV incidence between control (ART offered with CD4 below threshold) and intervention (ART offered to all) strategies. We assessed this incidence reduction using the revised (CD4 <500/µL) and prior (CD4 <350/µL) control ART initiation thresholds. Additionally, we evaluated changes to trial characteristics that could bolster the incidence reduction. Results: With a control ART initiation threshold of CD4 <350/µL, 24-month HIV incidence under control and intervention strategies was 2.46/100 person-years (PY) and 1.96/100 PY, a 21% reduction. Raising the threshold to CD4 <500/µL decreased the incidence reduction by more than one-third, to 12%. Using this higher threshold, moving to a 36-month horizon (vs 24-month), yearly control-strategy HIV screening (vs biannual), and intervention-strategy screening every 2 months (vs biannual), resulted in a 31% incidence reduction that was similar to effect size projections for ongoing trials. Alternate assumptions regarding cross-cluster contamination had the greatest influence on the incidence reduction. Conclusions: Implementing the 2013 WHO HIV treatment threshold could substantially diminish the incidence reduction in HIV population prevention trials. Alternative HIV testing frequencies and trial horizons can bolster this incidence reduction, but they could be logistically and ethically challenging. The feasibility of HIV population prevention trials should be reassessed as the implementation of treatment guidelines evolves. Key words: highly active antiretroviral therapy, HIV, prevention, randomized controlled trials

Over the past decade, antiretroviral therapy (ART) for HIV infection has greatly reduced HIV-related morbidity and mortality in resource-limited settings.1-5 In 2011, the HPTN 052 trial demonstrated that effective treatment could also dramatically reduce the risk of HIV transmission in stable serodiscordant sexual partnerships.6 Although the individual preventive impact of ART is clear, questions remain regarding the population-level effect of treatment-as-prevention in different settings. Ecological studies have shown conflicting results regarding the impact of ART scale-up on HIV incidence.7-10 The only nonecological evidence of the population-level effect of increasing ART coverage comes from a prospective population cohort in KwaZulu-Natal, South Africa. Controlling for behavioral, demographic, economic, and environmental risk factors, individual HIV acquisition risk declined significantly with increasing ART coverage both in the surrounding community11 and among household members of the opposite sex.12

To quantify the preventive benefits of expanded ART access more conclusively and to assess the feasibility of intensive treatment expansion programs, several trials of treatment-as-prevention are ongoing or planned.13-15 In general, these trials aim to randomize geographic clusters of a population to initiate ART based on national guidelines (control, typically CD4 <350/µL vs immediately upon diagnosis [intervention]); most also incorporate frequent routine HIV screening into the intervention. These trials are designed to assess differences in HIV incidence between treatment strategies, and several are powered to evaluate incidence reductions of around 30%.13,14

In June 2013, the World Health Organization (WHO) released updated guidelines for the use of ART, raising the recommended threshold for ART initiation from CD4 <350/µL to CD4 <500/µL in asymptomatic patients.18 This recommendation may prompt a change in national guidelines and trial protocols, leading to greater usage of ART in control clusters and potentially attenuating the difference in incidence between trial arms. Due to the longitudinal impact of policy changes, the incidence in the control arm and the incidence reduction between arms might be lower than planned and could thus require some compensation in trial design characteristics. We aimed to (a) quantify the impact that the revised ART initiation threshold could have on the outcomes of cluster-randomized, treatment-as-prevention trials and (b) assess how changes in trial characteristics could be used to augment the observed incidence reduction in the context of this policy change.

METHODS

Analytic Overview

We used 2 integrated HIV models to evaluate the outcomes of cluster-randomized population prevention trials. We first used the Cost-Effectiveness of Preventing AIDS Complications International (CEPAC-I) model,5,19,20 a patient-level microsimulation, to project survival, CD4 count, and HIV RNA trajectories of infected individuals. These trajectories then served as input to the HIV Dynamic Epidemiologic Framework (H-DEF) transmission model,21 a dynamic, open-cohort epidemic simulation.

We loosely modeled the base case of our analysis after a simplified version of the Agence Nationale de Recherches sur le Sida (ANRS) 12249 trial, an ongoing cluster-randomized population prevention trial conducted in rural KwaZulu-Natal, South Africa; the trial is powered for an effect size of 34%, based on previous detailed modeling analyses.13 (The ANRS 12249 trial incorporates a phased approach to enrollment and follow-up in 22 clusters. For simplicity, we do not simulate this phased approach and instead assume concurrent enrollment and follow-up.) Per trial protocol, we simulated 2 treatment strategies: (1) delayed ART initiation (control, at CD4 <350/µL) and (2) immediate ART initiation (intervention, at HIV diagnosis). Under both strategies, simulated individuals were offered home-based HIV screening at 6-month intervals. We projected HIV transmissions over a 24-month horizon under the 2 strategies and evaluated the relative reduction in cumulative HIV incidence (hereafter referred to as incidence reduction). Next, we assessed the impact that raising the control ART initiation threshold to CD4 <500/µL would have on this incidence reduction. We then evaluated how changes in the HIV screening frequencies and the time horizon of the trial could alter the incidence reduction in the context of this higher ART initiation threshold.

Transmission Model

To simulate trial outcomes, we developed a deterministic model of HIV transmission dynamics (H-DEF; see the eAppendix for details).21

The
randomly from independent distributions of age, sex, HIV RNA, and CD4 count. In the absence of treatment, individuals experience a monthly decline in CD4 count, increasing the risk of opportunistic diseases (ODs) and HIV-related mortality.

Previously unidentifiable individuals can be diagnosed with HIV in 2 ways: (1) presentation with an OD or (2) periodic routine testing. In simulating population prevention trials, other mechanisms of HIV testing (antenatal care, workplace programs, etc) are assumed to be captured under periodic routine testing. Participants diagnosed via presentation with an OD are assumed to accept testing and link to care. In the case of routine testing, however, individuals have a user-defined probability of being offered/accepting the HIV test and a probability of linking to care following a positive test. Those who fail to link are eligible for subsequent testing.

Following diagnosis/linkage, simulated patients are monitored with CD4 and HIV RNA tests at user-specified frequencies. ART is initiated when a patient’s observed CD4 count reaches a user-defined treatment threshold (specific to each trial strategy) or in the case of tuberculosis or WHO stage 3-4 disease; pregnancy is not simulated. Once on ART, patients are stratified by adherence level: highly adherent patients have a high probability of achieving virologic suppression, whereas poorly adherent patients have a low probability.25 While suppressed, patients experience monthly gains in CD4 count; they are also subject to a monthly probability of regimen failure and viral rebound. Failure leads to CD4 decline; when failure is diagnosed based on observed immunologic and/or virologic criteria,18,26 patients are switched to second-line ART or an adherence intervention is initiated. Any patient in care may be lost to follow-up; this risk declines with increasing adherence. Those who are lost to follow-up while on ART are assumed to discontinue therapy, but they may resume treatment upon return to care. Lost patients continue to contribute to HIV transmission rates within the simulated population.

Input Parameters

Transmission model inputs

HIV RNA–specific transmission rates (per 100 person-years [PY] with HIV) were derived from a meta-analysis of heterosexual serodiscordant couple studies (Table 1).22 We incorporated a 3-month

Note: ART = antiretroviral therapy; PY = person-years.

<sup>a</sup>The transmission rate multiplier is used to increase transmission rates observed among heterosexual serodiscordant couples to rates reflective of the general population.

<sup>b</sup>For sensitivity analysis, test offer and consent are combined into a single probability with base case value of 72%.

<sup>c</sup>Model input value derived from primary data described in reference.

<sup>d</sup>Overall suppression will be lower for second-line ART, as poorly adherent patients are more likely to fail first-line and initiate second-line.

<sup>e</sup>Only suppression at adherence >95% is varied in sensitivity analysis; overall suppression range indicates the range of overall suppression rates produced by variation in suppression at adherence >95%.

<sup>f</sup>Values for suppression, virologic failure, and loss to follow-up are linearly interpolated for adherence values between 5% and 95%; the value for 50% is provided.

<sup>g</sup>In sensitivity analysis, rates are varied in concert at high and low adherence levels.
acute HIV infection phase, during which infectivity is increased 26-fold relative to chronic infection.\textsuperscript{27} Per estimates in the ANRS trial protocol, we assumed 10% cross-cluster contamination\textsuperscript{13} (ie, 10% of participants’ sexual partners will be outside of their own cluster type) and varied this widely in sensitivity analysis.

**Natural history**

CD4-specific rates of morbidity and mortality were from the Cape Town AIDS Cohort.\textsuperscript{28} Patients in care received cotrimoxazole prophylaxis at CD4 <200/µL,\textsuperscript{29} generally reducing OD risk.\textsuperscript{30,31}

**HIV testing**

Per trial protocol, HIV tests were offered every 6 months in both control and intervention clusters.\textsuperscript{13} In each 6-month round of screening, we assumed 90% of individuals would be offered an HIV test, 80% would consent to the test, and 70% of those testing positive would link to care, which was consistent with testing experience from preliminary trial data.\textsuperscript{32} We account for the “window period” of infection by assuming that HIV tests give negative results during the first month after infection (due to acute infection) and have 100% sensitivity thereafter.\textsuperscript{33,34}

**Population**

At baseline, modeled adult (≥15 years) HIV prevalence was 23%, which was consistent with data from KwaZulu-Natal.\textsuperscript{35,36} Thirty-three percent of HIV-infected individuals were assumed to be undiagnosed (with 3% acutely infected),\textsuperscript{37} 41% were diagnosed but not on ART, 25% were on first-line ART, and 1% were on second-line ART, based on data from the Africa Centre Demographic Information System and other South African sources (eFigure 2).\textsuperscript{38-40} Among these baseline states, simulated mean (SD) CD4 varied from 380 (190) cells/µL for those on ART to 560 (230) cells/µL for those with acute infection (Table 2).\textsuperscript{37,41,42} We assumed that individuals who were eligible for but not on ART at baseline would initiate therapy with a monthly probability of 15%, reflecting enhanced efforts to provide access to ART in the context of a trial.\textsuperscript{13}

**ART efficacy**

Six-month virologic suppression was assumed to be 91% for patients with adherence >95% (defined by medication possession ratio) and 0% with adherence <5%; linear interpolation was used for intermediate adherence levels.\textsuperscript{43} This leads to ~80% overall suppression at 6 months, consistent with outcomes in KwaZulu-Natal.\textsuperscript{44} After 6 months, virologic failure rates ranged from 1.6 to 150/100 PY, depending on adherence. Patients with virologic rebound on first-line ART received an adherence intervention, leading to resuppression for ~50% of them (see the eAppendix).\textsuperscript{45} Those who did not resuppress were switched to a second-line regimen, after which there were 2 additional opportunities to resuppress with adherence interventions of decreasing efficacy.\textsuperscript{46} Though previous failure to suppress on a regimen is not

\textsuperscript{a}Baseline population distribution is derived from data in references 34-37 (see eFigure 2).

\textsuperscript{b}CD4 distributions are truncated normal distributions calibrated to match data from references 41 (acute infection), 37 (undiagnosed, chronic), and 42 (off ART, first-line, and second-line).
explicitly tracked in the model, failed patients have lower probabilities of regaining suppression after an increasing number of failure events. This feature is intended to capture some of the effects of resistance. The development of ART resistance is not explicitly modeled.

**Loss to follow-up**

We used adherence-specific relative rates of loss to follow-up and calibrated the absolute rates to match the 4% loss at 12 months on ART observed in KwaZulu-Natal. As individuals at highest risk for loss to follow-up are removed from the in-care population over time, overall rates of loss to follow-up decline, resulting in 7% lost at 24 months. Patients ineligible for ART due to high CD4 count are subject to a higher risk of loss to follow-up across all adherence levels, consistent with the 45% pre-ART retention observed in KwaZulu-Natal. Lost patients were assumed to have a 0.75% monthly probability of returning to care and a 50% probability of return upon experiencing an acute OD.

**Transmission Model Calibration**

Before modeling the cluster-randomized trial, the transmission model was calibrated to historical HIV prevalence and incidence trends in KwaZulu-Natal using 2 calibration parameters governing (1) HIV RNA–specific transmission rates and (2) sexual mixing patterns in the population. The first parameter (Table 1) is used to increase the transmission rates observed in serodiscordant couple studies to a level reflective of the overall population, whereas the second accounts for the effects of nonrandom sexual mixing (eTable 1; see eAppendix for more details).

**Alternative Trial Characteristics**

We examined several potential changes to trial protocol that could bolster a trial’s incidence reduction in the context of an ART initiation threshold of CD4 <500/µL for the control strategy. These included alternative settings characterized by differing frequencies of HIV screening in the control strategy (every 6, 12, 24, or 36 months), increasing the frequency of HIV screening in the intervention strategy (every 1, 2, 4, or 6 months), and extending the trial duration (24-, 36-, or 48-month horizons). For reporting purposes, we selected combinations of these changes to create 3 composite scenarios:

1. **Initial**: Screening every 6 months in both strategies and a 24-month horizon, reflecting the initial design of the ANRS 12249 trial.
2. **Intensified**: Screening every 2 months in the intervention strategy, yearly screening in the control strategy, and a 36-month horizon.
3. **Maximal**: Monthly screening in the intervention strategy, screening every 3 years in the control strategy, and a 48-month horizon.

Testing intervals as short as 1 month in the intervention strategy may not be feasible, but these extreme frequencies serve to provide an upper limit on the trial incidence reduction.

Testing intervals as short as 1 month in the intervention strategy may not be feasible, but these extreme frequencies serve to provide an upper limit on the trial incidence reduction.

Certain model parameters were derived from sub-Saharan African countries other than South Africa. To assess the impact of input parameter uncertainty and cross-country variability on our conclusions, we projected HIV incidence while varying model parameters in both trial strategies over the ranges shown in Tables 1 and 2 and eTable1. Additionally, we selected several model parameters that could most plausibly be affected by the implementation of immediate ART (linkage to care, initial suppression on first-line ART, loss to follow-up) and varied these parameters by a factor of ±20% under the intervention strategy only.

**RESULTS**

**Calibration**

The model was able to produce a close fit to historical prevalence, incidence, and ART rollout data from 1990 to 2011 in KwaZulu-Natal (Figure 1). At the baseline of the analysis in 2013, projected HIV incidence was 3.41/100 PY, which was consistent with published data estimates from KwaZulu-Natal. Six months after initiating the trial treatment strategies, ART coverage increased to 50% when an initiation threshold of CD4 <350/µL was used, consistent with levels achieved in an intensive home-based testing program in KwaZulu-Natal.
Figure 1. HIV Dynamic Epidemic Framework (H-DEF) model calibration and projections. Figure 1A depicts historical and projected HIV prevalence and incidence in KwaZulu-Natal from 1990 to 2020 in the H-DEF model, compared to 3 outside data sources: (1) the Actuarial Society of South Africa (ASSA) 2008 model, (2) adjusted HIV prevalence estimates from the Africa Center Demographic Information System, and (3) HIV incidence estimates from a large population-based longitudinal HIV surveillance study. Though the ASSA 2008 model gives both lower prevalence and lower incidence estimates than the model calibration, ASSA 2008 is reported to underestimate both parameters.

Figure 1B depicts antiretroviral therapy (ART) coverage in KwaZulu-Natal from 2004 to 2020 in the H-DEF model compared to (1) estimates from the Africa Center Demographic Information System (Zaidi), and (2) initial and 6-month ART coverage estimates from a home-based testing program in KwaZulu-Natal, used as a rubric for how rapidly ART coverage could increase in the context of home-based testing within a trial. In both figures, the dashed vertical line indicates the start of the simulated trial. To the right of the vertical line are model projections of adult HIV prevalence and incidence and ART coverage with ART initiation criteria of CD4 ≤350/µL (dotted line), CD4 ≤500/µL (solid gray line), and immediate (dashed line).
Initial Trial Design

Over the 24-month horizon, we projected an HIV incidence of 2.46/100 PY with the control strategy and 1.96/100 PY with the intervention, for an incidence reduction of 21%. If the ART initiation threshold in control clusters were raised to CD4 <500/µL, 24-month HIV incidence would fall for both strategies due to cross-cluster contamination to 2.17/100PY with the control strategy and 1.90/100PY with the intervention, decreasing the incidence reduction between strategies by more than a third (incidence reduction = 12%) (Table 3, top).

With a control ART threshold of CD4 <350/µL, 41% of HIV-infected individuals in control clusters were not on ART after 12 months; in the intervention clusters, only 17% were not on ART. This resulted in a relative reduction in individuals off ART of 59%. Raising the ART threshold in the control strategy attenuated the differences in ART coverage between the strategies; with a threshold of CD4 <500/µL, the relative reduction in individuals off ART fell to 43% (Table 3, bottom).

Sensitivity analysis

Raising the control ART threshold to CD4 <500/µL consistently decreased the incidence reduction across wide variation in input parameters (Figure 2A). At all parameter values evaluated, the incidence reduction was lower with a threshold of CD4 <500/µL than with a threshold of 350/µL; one-third to one-half of the total incidence reduction was lost when the higher ART initiation threshold was used.

Table 3. Base case results

Note: ART = antiretroviral therapy; PY = person-years.

*The relative reduction in HIV incidence between intervention and control strategies is equivalent to trial effect size.

*Due to cross-cluster contamination, incidence in the intervention strategy is affected by the ART initiation threshold in the control strategy.

Alternative Trial Characteristics

In general, greater incidence reductions were associated with settings with less frequent HIV screening in the control strategy, more frequent screening in the intervention strategy, and longer trial time horizon (Figure 3). The intensifi ed scenario (Figure 3, middle panel, circle) produced an incidence reduction of 31%; the maximal scenario (Figure 3, right panel, triangle) produced an incidence reduction of 41%. Similar trends with respect to the trial design parameters were observed when an ART initiation threshold of CD4 <350/µL was used (eFigure 5). Notably, the 3 scenarios responded differently to the change from an ART initiation threshold of CD4 <350/µL to 500/µL: the incidence reduction in the initial scenario decreased by a relative 40% (21% to 12%), that of the intensifi ed scenario decreased by 17% (37% to 31%), and that of the maximal scenario decreased by only 9% (45% to 41%).

Sensitivity analysis

For all 3 of the trial design scenarios selected, the parameter with the greatest impact on the incidence reduction was related to cross-cluster contamination (Figure 2B). When contamination was varied between 0% and 20%, the incidence reduction in the initial scenario (at a threshold of CD4 <500/µL) ranged from 17% to 8%, the incidence reduction in the intensifi ed scenario decreased by a relative 40% (21% to 12%), that of the intensified scenario decreased by 17% (37% to 31%), and that of the maximal scenario decreased by only 9% (45% to 41%).

Figure 2. Sensitivity analysis on model input parameters. Observed incidence reduction is shown for varying values of select model input parameters; the 7 parameters with the greatest effect on projected results are shown in the figure. The width of each horizontal bar indicates the variation in incidence reduction when varying a particular model parameter over the range (corresponding left to right) denoted in the label in parentheses on the vertical axis; wider bars indicate that the incidence reduction is more sensitive to that particular parameter. Dashed vertical lines indicate the incidence reduction observed with base case inputs. Figure 2A shows the incidence reduction with the initial scenario at control antiretroviral therapy (ART) initiation thresholds of CD4 <350/µL (light gray) and CD4 <500/µL (dark gray). Figure 2B shows the incidence reduction with the initial (dark gray), intensified (medium gray), and maximal (light gray) scenarios at a control ART initiation threshold of CD4 <500/µL. For the initial scenario, the incidence is greater with acute infection duration of 2 months or 6 months compared to the base case value of 3 months.
On occasion, policy changes are based on best possible evidence that falls short of the “gold standard” randomized clinical trial. When this occurs, clinical trials designed to provide that evidence can become that much more challenging to conduct, as evidenced by this study.

Using a dynamic mathematical modeling approach, we projected that implementing the ART initiation threshold of CD4 $<500/\mu L$ suggested by the new WHO guidelines\textsuperscript{18} reduces the incidence reduction in HIV population prevention trials by one-third to one-half. Altered characteristics—especially more frequent HIV screening in the intervention strategy compared to the control strategy—produced greater incidence reductions. Notably, we projected that a trial scenario with intervention-strategy screening every 2 months and control-strategy screening every year would produce a 31% incidence reduction at 36 months, consistent with the effect size that several population prevention trials are currently powered to detect.\textsuperscript{13,14}

Although we found that differential HIV screening frequencies could efficiently amplify the

\caption{Incidence reduction with varying trial characteristics. Projected trial incidence reduction with an antiretroviral therapy (ART) initiation threshold of CD4 $<500/\mu L$ and varying combinations of control strategy HIV test frequency (6-36 months), intervention strategy HIV test frequency (1-6 months), and trial horizon (24-48 months). The shading at each point in the figure denotes the projected incidence reduction with that combination of trial design characteristics. Three scenarios are highlighted for further analysis (see Methods section for descriptions of these scenarios): (1) initial, square; (2) intensified, circle; (3) maximal, triangle. The predicted incidence reduction for each of these scenarios is shown in the legend.}
\end{figure}
observed incidence reduction, we recognize that implementing this will not be straightforward. Increasing testing frequency in intervention arms will be logistically challenging (and could lead to lower test acceptance), and maintaining reduced testing frequencies in control arms may pose ethical concerns. Because HIV screening is also the method of ascertaining trial outcomes, differential screening frequencies will also need to be accounted for when analyzing results. Moreover, the bolstered incidence reduction may come at the cost of interpretability of results. A trial in which strategies differ only in the choice of ART initiation threshold is definitively a trial of treatment-as-prevention, and differences between the 2 strategies can be attributed to the ART initiation threshold alone. With differential screening rates incorporated as well, some of the incidence reduction would clearly be due to HIV testing; this would now be a trial of test-and-treat. Further, although we did not evaluate additional preventive interventions (male circumcision, condom provision, prevention of mother-to-child transmission, etc), some planned cluster-randomized trials will incorporate these into combined interventions, with some varying interventions – including testing frequency – across more than 2 arms. Extrapolating from our results, we can expect that the effect of these combination interventions may prove relatively robust to changes in ART initiation threshold. However, it will be essential to weigh the benefits of this bolstered incidence reduction against the potential to further complicate the interpretation of trial results.

In sensitivity analysis, we found that implementing the new ART initiation threshold produced consistent decreases in the incidence reduction across a wide range of parameter values; likewise, differences between the alternative trial scenarios simulated were robust to parameter variation. However, absolute incidence reductions were particularly sensitive to variation in certain parameters. Reductions in the rate of HIV test acceptance, the likelihood of linkage-to-care after a positive test, and the baseline proportion of the population with undiagnosed HIV attenuated the differences in ART coverage between the 2 trial strategies and thus decreased the incidence reduction. This result is consistent with findings from prior trials of HIV prevention strategies such as microbicides, in which “overlap” of an intervention to the control arm has been a common barrier to achieving a significant incidence reduction. In this case, overlap is manifested in increasing control arm ART coverage; in our analysis, a greater overlap (ie, a smaller difference in ART coverage between strategies) was associated with a diminished incidence reduction. These findings imply that ongoing monitoring of ART coverage will prove valuable in interpreting the results of population prevention trials.

Cross-cluster contamination also proved to be highly influential on trial outcomes. This finding highlights the importance of selecting trial settings in which communities are relatively sexually isolated (such as rural KwaZulu-Natal), and it suggests that a priori measurement of the likelihood of contamination (via survey or genetic linkage testing) will be critical to assessments of the feasibility of a given trial. Settings in which a high degree of contamination is likely may be suitable for studying interventions targeted to negative individuals, but will likely be inappropriate for interventions targeted to persons with HIV.

This analysis has several limitations. First, we note that the clinical trial strategies simulated here are only loosely based on the ANRS 12249 trial; our results should not be interpreted as projections of the potential outcome of that trial specifically. Due to the complexity of our combined disease progression and transmission models, we have not performed direct trial simulations and did not make effect size/sample size calculations. Next, our model of HIV transmission is neither age- nor sex-stratified and does not explicitly account for behavioral factors such as concurrent sexual partnerships or sexual networks. Likewise, sex differences in HIV testing frequency and ART uptake are not explicitly modeled. Thus, if trial interventions are rolled-out unevenly to individuals who differ in these predictors of transmission risk, our model may fail to capture the implications for HIV incidence. For example, current ART coverage is comparatively low among more sexually active younger individuals; increasing coverage in this group could lead to a disproportionately large reduction in incidence. Additionally, we did not model the potential for expanded HIV treatment and/or poor ART adherence to produce an increase in transmitted drug resistance. Transmitted resistance could affect long-term outcomes of expanded ART policies, but this omission is unlikely to bias our short-term incidence projections. Finally, we
note that the value of expanded HIV treatment and prevention programs will depend on their long-term population-level costs and clinical impact, not just their short-term impact on HIV transmission.57-59 Thus, the results of this analysis, and of the cluster-randomized trials we have modeled, will be an imperfect indicator of the full, long-term benefits of treatment-as-prevention.

Our modeling analysis suggests that increasing the control ART initiation threshold from CD4 <350/µL to CD4 <500/µL could substantially reduce the incidence reduction observed in HIV population prevention trials. Even though it may take some time for this change to be implemented in national treatment guidelines and trial protocols, it is critical to begin preparing for it now. The feasibility of ongoing trials may need to be reevaluated, and potential changes to trial protocol and sample size to preserve effect size should be considered.
