Abstract. The spring bloom is a key annual event in the phenomenology of pelagic ecosystems, making a major contribution to the oceanic biological carbon pump through the production and export of organic carbon. However, there is little consensus as to the main drivers of spring bloom formation, exacerbated by a lack of in situ observations of the phytoplankton community composition and its evolution during this critical period.

We investigated the dynamics of the phytoplankton community structure at two contrasting sites in the Iceland and Norwegian basins during the early stage (25 March–25 April) of the 2012 North Atlantic spring bloom. The plankton composition and characteristics of the initial stages of the bloom were markedly different between the two basins. The Iceland Basin (ICB) appeared well mixed down to >400 m, yet surface chlorophyll a (0.27–2.2 mg m⁻³) and primary production (0.06–0.66 mmol C m⁻³ d⁻¹) were elevated in the upper 100 m. Although the Norwegian Basin (NWB) had a persistently shallower mixed layer (<100 m), chlorophyll a (0.58–0.93 mg m⁻³) and primary production (0.08–0.15 mmol C m⁻³ d⁻¹) remained lower than in the ICB, with picoplankton (<2 µm) dominating chlorophyll a biomass. The ICB phytoplankton community was potentially limited by physicochemical and/or biological factors such as grazing.

Diatoms dominated the ICB, with the genus Chaetoceros (1–166 cells mL⁻¹) being succeeded by Pseudo-nitzschia (0.2–210 cells mL⁻¹). However, large diatoms (>10 µm) were virtually absent (<0.5 cells mL⁻¹) from the NWB, with only small nano-sized (<5 µm) diatoms (i.e. Minidiscus spp.) present (101–600 cells mL⁻¹). We suggest microzooplankton grazing, potentially coupled with the lack of a seed population of bloom-forming diatoms, was restricting diatom growth in the NWB, and that large diatoms may be absent in NWB spring blooms. Despite both phytoplankton communities being in the early stages of bloom formation, different physicochemical and biological factors controlled bloom formation at the two sites. If these differences in phytoplankton composition persist, the subsequent spring blooms are likely to be significantly different in terms of biogeochemistry and trophic interactions throughout the growth season, with important implications for carbon cycling and organic matter export.
1 Introduction

The spring bloom is a key annual event in the phenology of pelagic ecosystems, where a rapid increase in phytoplankton biomass has a significant influence on upper ocean biogeochemistry and food availability for higher trophic levels (Townsend et al., 1994; Behrenfeld and Boss, 2014). Spring blooms are particularly prevalent in coastal and high-latitude waters. The high levels of phytoplankton biomass and primary production that occur during these blooms, and its subsequent export out of the surface ocean, result in a significant contribution to the biological carbon pump (Townsend et al., 1994; Sanders et al., 2014). The North Atlantic spring bloom is one of the largest blooms on Earth, making a major contribution to the annual export of $\sim 1.3 \text{ Gt C yr}^{-1}$ from the North Atlantic (Sanders et al., 2014).

Phytoplankton blooms occur when growth rates exceed loss rates (i.e. a sustained period of net growth); phytoplankton growth rate constraints include irradiance, nutrient supply, and temperature, while losses can occur through predation, advection, mixing out of the euphotic zone, sinking, and viral attack (Miller, 2003). Therefore, the rapid increase in (net) growth rates during the spring bloom must be due to either an alleviation of those factors constraining growth, a reduction in factors determining losses, or (more likely) some combination of both.

The critical depth hypothesis (Sverdrup, 1953), the seminal theory of spring bloom initiation, proposes that there exists a critical depth such that when stratification shoals above this depth, phytoplankton growth will exceed mortality and a bloom will occur. However, this hypothesis has been more recently brought into question as bloom formation has been observed to start earlier than expected (Mahadevan et al., 2012) and in the absence of stratification (Townsend et al., 1992; Eilertsen, 1993). Several new theories have now been developed to explain these occurrences (reviewed in Behrenfeld and Boss, 2014; Fischer et al., 2014; Lindemann and St. John, 2014).

Eddies and oceanic fronts have both been identified as sources of stratification prior to the wider onset of seasonal stratification (Taylor and Ferrari, 2011a; Mahadevan et al., 2012). However, they do not explain blooms in the complete absence of stratification, which can instead be explained by the critical turbulence hypothesis (Huisman et al., 1999; Taylor and Ferrari, 2011b; Brody and Lozier, 2014; Smyth et al., 2014). These theories distinguish between a convectively driven actively mixed layer and a density-defined mixed layer such that if convective mixing reduces sufficiently, blooms can occur in the actively mixing layer although the density-defined mixing layer remains deep. Therefore, blooms are able to form in the apparent absence of stratification, as defined by the presence of a thermocline. An alternative to the hypotheses concerning physical controls on bloom formation is the disturbance–recovery hypothesis proposed by Behrenfeld (2010), which suggests that the decoupling of phytoplankton and microzooplankton contact rates in deep winter mixed layers results in phytoplankton net growth from winter onwards due to reduced mortality (via grazing). It is also possible that there are multiple biological and physical controls, acting on different spatial and temporal scales, that drive the heterogeneous bloom distributions observed via remote sensing (e.g. Lindemann and St. John, 2014).

Significant interannual and decadal variability in the structure and timing of spring blooms in the North Atlantic has been documented (Henson et al., 2009). Such variability in bloom timing has been attributed to the variation in the winter mixed layer depth (WMLD); a deeper WMLD results in a delayed bloom in the subarctic North Atlantic (Henson et al., 2009). A strong latitudinal trend exists in the North Atlantic where the spring bloom propagates north due to seasonal relief from light limitation at high latitudes (Siegel et al., 2002; Henson et al., 2009). Both the role of the WMLD in interannual variability in bloom timing and the northwards progression of bloom start dates highlight how physical processes have a clear and significant impact on bloom formation. The controls on the variability in bloom magnitude are less certain, although it appears to be a combination of WMLD variability influencing the start date as well as biological factors such as phytoplankton composition and grazing (Henson et al., 2009).

Despite considerable discussion on the various factors that may or may not influence bloom initiation, timing, magnitude and phenology, few studies have actually examined the in situ phytoplankton community. Instead, because of the need for temporally resolved data, satellite-derived products and models have been used in much of the previous work on spring blooms. However, such methods cannot address the potential influence of the complex plankton community structure on the development of a spring bloom.

The traditional textbook view of a phytoplankton spring bloom is that the pre-bloom pico-phytoplankton-dominated (cells $< 2 \mu$m) community is directly succeeded by a diatom-dominated community (Margalef, 1978; Barber and Hiscock, 2006); as conditions become more favourable for growth, a diatom bloom develops, "suppressing" the growth of other phytoplankton groups. Through either increased predation, nutrient stress, or a changing physical environment (Margalef, 1978), diatoms decline and are then replaced by other phytoplankton such as dinoflagellates and coccolithophores (Lofte et al., 1993; Leblanc et al., 2009). In this way, a series of phytoplankton functional type successions occur as the spring bloom develops. That diatoms often dominate in-
tense spring blooms is well accepted (Lochte et al., 1993; Rees et al., 1999); however, the dynamics of the interplay between diatoms and the rest of the community have been questioned (Barber and Hiscock, 2006). The rapid proliferation of diatoms in a spring bloom does not necessarily suppress other phytoplankton (Lochte et al., 1993; Barber and Hiscock, 2006), and the “rising tide” hypothesis states that instead of succession, the favourable conditions for diatoms also favour other phytoplankton groups, and therefore all phytoplankton will respond positively and grow (Barber and Hiscock, 2006). The apparent suppression of the phytoplankton community by diatoms is due to the relatively high intrinsic growth rates of diatoms resulting in concentrations dwarfing the rest of the community. The rising tide hypothesis is a contrasting theory to succession; however, it may be that the phytoplankton community response will not be universal, with some taxa-specific succession due to competition or increased grazing (Brown et al., 2008). Furthermore, succession may appear to occur if phytoplankton loss rates are taxonomically specific, such that while many phytoplankton groups concurrently grow, successive loss of specific groups occurs.

The overall goal of our study was to determine the phytoplankton community structure, and its evolution during the spring bloom in the North Atlantic, linking the community structure to the physical environment and examining whether succession to a diatom-dominated environment would occur early in the growth season (March–April). Sampling for this study was carried out as part of the multidisciplinary EuroBASIN “Deep Convection Cruise”. The timing and location of this cruise (19 March–2 May 2012) was chosen to try to observe the transition from deep winter convection to spring stratification, and examine the physical controls on the dynamics of phytoplankton, carbon export, and trophic interactions. A recent study has previously suggested that winter convection in the North Atlantic and Norwegian Sea sustains an overwintering phytoplankton population, thus providing an inoculum for the spring bloom (Backhaus et al., 2003), although this transition has not been explicitly examined before.

2 Methods

2.1 Sampling

The Deep Convection Cruise repeatedly sampled two pelagic locations in the North Atlantic (Fig. 1), situated in the Iceland (ICB, 61.50° N, 11.00° W) and Norwegian (NWB, 62.83° N, 2.50° W) basins, onboard the R/V Meteor. The ICB was visited four times, and the NWB visited three times during the course of the cruise. Samples were collected from multiple casts of a conductivity–temperature–depth (CTD) Niskin rosette, equipped with a fluorometer, at each station. Water samples for rates of primary production (PP), community structure, and ancillary parameters (chlorophyll a (Chl a), calcite (PIC), particulate silicate (bSiO2), and macronutrient concentrations) were collected from predawn (02:30–05:00 GMT) casts from six light depths (55, 20, 14, 7, 5, and 1 % of incident PAR). The depth of 1 % incident irradiance was assumed to equate to the depth of the euphotic zone (e.g. Poulton et al., 2010). Optical depths were determined from a daytime CTD cast on preceding days at each site. Additional samples for coccolithophore community structure and ancillary parameters were collected from a second CTD cast, while samples for detailed size-fractionated Chl a were collected from a third cast.

2.2 Primary production

Carbon fixation rates were determined using the 13C stable isotope method (Legendre and Gosselin, 1996). Water samples (1.2 L) collected from the six irradiance depths were inoculated with 45–46 μmol L−1 13C labelled sodium bicarbonate, representing 1.7–1.8 % of the ambient dissolved inorganic carbon pool. Samples were incubated in an on-deck incubator, chilled with sea surface water, and light depths were replicated using optical filters (misty-blue and grey, LEE™). Incubations were terminated after 24 h by filtration onto pre-ashed (> 400 °C, > 4 h) Whatman GF/F filters. Acid-labile particulate inorganic carbon (PIC) was removed by adding 1–2 drops of 1 % HCl to the filter followed by extensive rinsing with freshly filtered (Fisherbrand MF300, ~ 0.7 μm pore size) unlabelled seawater. Filters were oven dried (40°C, 8–12 h) and stored in Millipore PetriSlides™. A parallel 55 % control bottle for size-fractionated primary production (< 10 μm) was incubated alongside the other samples, with the incubation terminated by pre-filtration through 10 μm polycarbon-
ate (Nuclepore™) filters and the filtrate was filtered and processed as above.

The isotopic analysis was performed on an automated nitrogen and carbon analysis preparation system with a 20–20 stable isotope analyser (PDZ Europa Scientific Instruments). The $^{13}$C-carbon fixation rate was calculated using the equations described in Legendre and Gosselin (1996). The $>10 \mu m$ PP fraction was calculated as the difference between total PP and $<10 \mu m$ PP.

2.3 Community structure

Water samples for diatom and microzooplankton counts, collected from predawn cast surface samples (5–15 m) were preserved with acidic Lugol’s solution (2% final solution) in 100 mL amber glass bottles. Cells were counted in 50 mL Hydro-Bios chambers using a Brunel SP-95-1 inverted microscope (X200; Brunel Microscopes Ltd). Samples for flow cytometry were fixed with glutaraldehyde (0.5% final solution) and stored at $-80^\circ$C before being analysed using a FACSCalibur (Beckton Dickinson) flow cytometer (Zubkov et al., 2007).

Water samples (0.5–1 L) for coccolithophore cell numbers and species identification were collected from surface samples (5–15 m) onto cellulose nitrate filters (0.8 µm pore size; Whatman), oven dried, and stored in Millipore PetriSlides™. Permanent slides of filter halves were prepared and analysed using polarising light microscopy following Poulton et al. (2012). Coccolithophores were analysed at the species level following Frada et al. (2010). For confirmation of species identification, a subset of filter halves were analysed by scanning electron microscope (SEM) following Daniels et al. (2012). Coccolithophore species were identified according to Young et al. (2003).

2.4 Chl $a$

Water samples (250 mL) for total Chl $a$ analysis were filtered onto Fisherbrand MF300 filters. Parallel samples were filtered onto polycarbonate filters (10 µm) for $>10 \mu m$ Chl $a$. Samples for detailed size-fractionated Chl $a$, collected in duplicate from a single depth in the upper water column (12–35 m), were filtered in parallel onto polycarbonate filters of various pore size (2, 10, 20 µm) and MF300 filters (effective pore size 0.7 µm). Filters were extracted in 8 mL of 90% acetone (Sigma) for 20–24 h (dark, $4^\circ$C). Measurements of Chl $a$ fluorescence were analysed on a Turner Designs Trilogy Fluorometer, calibrated using a solid standard and a Chl $a$ extract.

2.5 Ancillary parameters

Particulate inorganic carbon (PIC) measurements were made on water samples (500 mL) filtered onto polycarbonate filters (0.8 µm pore-size, Whatman), rinsed with trace ammonium solution (pH ∼ 10) and oven dried (6–8 h, 30–40°C). The analysis was carried out following Daniels et al. (2012) except that extractions were carried out in 5.0 mL of 0.4 mol L$^{-1}$ nitric acid, erroneously reported as 0.5 mL in Daniels et al. (2012). Particulate silicate (bSiO$_2$) samples were collected onto polycarbonate filters (0.8 µm pore-size, Whatman), rinsed with trace ammonium solution (pH ∼ 10) and oven dried (6–8 h, 30–40°C). Digestion of bSiO$_2$ was carried out in polypropylene tubes using 0.2 mol L$^{-1}$ sodium hydroxide, before being neutralised with 0.2 mol L$^{-1}$ hydrochloric acid (Ragueneau and Tréguer, 1994; Brown et al., 2003). The solutions were analysed using a SEAL QuAAtro autoanalyser, and no corrections were made for lithogenic silica. Macronutrients (nitrate, phosphate, silicic acid) concentrations were determined following Sanders et al. (2007) on a Skalar autoanalyser.

Samples for total dissolved inorganic carbon (C$_T$) were drawn into 500 mL borosilicate bottles. No filtering of samples occurred prior to analysis. Samples were stored in the dark and analysed within 12 h of sampling, and thus no poisoning was required. C$_T$ was determined using coulometric titration (Johnson et al., 1987) with a precision of $<2 \mu mol kg^{-1}$. Measurements were calibrated against certified reference material (CRM, Dickson, 2010). Seawater pH$_T$ was measured using the automated marine pH sensor (AMPS) system as described in Bellerby et al. (2002) modified for discrete mode. This system is an automated spectrophotometric pH sensor that makes dual measurements of thymol blue. The pH$_T$ data used in this study were computed using the total hydrogen ion concentration scale and have a precision of 0.0002 pH$_T$ and an estimated accuracy of better than 0.0025 pH$_T$ units against CRM standards. The measured C$_T$ and pH$_T$, with associated temperatures and salinity, were input to CO2SYS (Lewis and Wallace, 1998) to calculate saturation state of CaCO$_3$ using the dissociation constants for carbonic acid of Dickson and Millero (1987), boric acid from Dickson (1990b), sulfuric acid following Dickson (1990a) and the CO$_2$ solubility coefficients from Weiss (1974).

Satellite data on Chl $a$, photosynthetically available radiation (PAR), and sea surface temperature (SST) were obtained from the Aqua Moderate Resolution Image Spectroradiometer (MODIS) as 4 km resolution, 8-day composites. Data were extracted as averaged $3 \times 3$ pixel grids, centred on the sampling locations. Day length was calculated according to Kirk (1994). The R/V Meteor was not fitted with a PAR sensor, and thus satellite measurements were the only available source of PAR data.

2.6 Data availability

Data included in the paper are available from the data repository PANGAEA via Daniels and Poulton (2013) for the measurements of primary production, Chl $a$, particulate inorganic carbon, particulate silicate, cell counts of coccolithophores, diatoms, and microzooplankton; Esposito and Martin (2013) for measurements of nutrients; Poulten et al.
Figure 2. Upper water column profiles for the ICB (a, b, c) and the NWB (d, e, f), of density (a, d), CTD fluorescence (b, e), and CTD fluorescence normalised to peak CTD fluorescence for each profile (c, f).

al. (2014) for measurements of picoplankton and nanoplan-
kt; and Bellerby (2014) for measurements of the carbonate
chemistry.

3 Results

3.1 General oceanography

The two sites were characterised by very different water col-
umn profiles throughout the study period. In the NWB, a pyc-
nocl ine persisted over the upper 400 m with a variable mixed
layer (20–100 m, Fig. 2d). In contrast, the ICB appeared well
mixed over the upper 400 m when considered over the equiv-
alent density range (Fig. 2a). However, weak unstable strat-
ification was observed in the upper 100 m when examined
over a much narrower range in density (Fig. 2a inset).

Sea surface temperature showed little variation at both
sites (Table 1), while the ICB (8.6–8.9 °C) was consistently
warmer than the NWB (6.5–7.2 °C). Satellite estimates of
SST were colder than in situ measurements and exhibited
greater variability (Fig. 3a). However, the general pattern of
the ICB being warmer than the NWB was observed from
both in situ measurements and satellite-derived ones. Sea-
surface salinity (SSS), pH, and ΩCa were relatively stable
throughout the study with total ranges of 35.1–35.3, 8.0–8.1,
and 3.0–3.2, respectively (Table 1).

Initial surface water concentrations of nitrate (NO₃) and
phosphate (PO₄) were ~12 mmol N m⁻³ and ~0.7–

0.8 mmol P m⁻³ at both sites (Table 1). Silicic acid (dSi)
was high throughout the study period (mostly >4 mmol
Si m⁻³), with slightly higher concentrations in the NWB
(5.3–5.7 mmol Si m⁻³) than the ICB (<5 mmol Si m⁻³).

Drawdown of 1 mmol m⁻³ of NO₃ and dSi occurred in the
ICB between 19 and 27 April, but then returned to previous
levels by 29 April. Nutrient drawdown did not occur in the
NWB during the cruise period.

Both sites showed a similar trend of increasing daily
PAR during the study (Fig. 3b): a twofold increase in the
NWB (from 12.3 to 28.4 mol quanta m⁻² d⁻¹) and a
slightly smaller increase in the ICB (from 13.5 to 24.3 mol
quanta m⁻² d⁻¹). Daily irradiance continued to increase after
the cruise finished, peaking around 40–45 days later at val-
ues in excess of 40 mol quanta m⁻² d⁻¹ (Fig. 3b). The gen-
eral trend of increasing PAR was also reflected in the day
length (Fig. 3b). At both sites, the euphotic depth shoaled as
the study progressed, from 115 to 50 m in the ICB and from
80 m to 56 m in the NWB (Table 2). However, the euphotic
depth again deepened by 36 m between the third and fourth
visits to the ICB.

For the duration of the cruise until 27 April (day 118), sur-
face and euphotic zone integrated particulate silicate (bSiO₂)
increased in the ICB, peaking at 0.66 and 37.1 mmol Si m⁻²,
respectively (Fig. 4a, Table 2), with a significant decline in
bSiO₂ after this date. Lower values of bSiO₂, with little tem-
poral variation, were found in the NWB, although a small
increase in surface bSiO₂ was observed between 14 and
22 April (from 0.05 to 0.08 mmol Si m⁻³, Fig. 4a). Stand-
ing stocks of PIC were less variable than bSiO₂. The high-
est surface values were observed during the last visit to the
NWB (0.20 mmol C m⁻³), while integrated calcite peaked at
11 mmol C m⁻² on 27 April in the ICB (Table 2).

3.2 Chlorophyll a

Profiles of CTD fluorescence in the NWB had a relatively
consistent structure with high fluorescence in the stratified
upper water column (Fig. 2e and f). Intra-site variation can
be seen in the relative fluorescence values in surface waters,
but a consistent increase over time was not observed. Flu-
orescence profiles in the ICB were more variable (Fig. 2b
and c), ranging from profiles with high surface fluorescence
(10 April, day 101) to profiles with elevated fluorescence
throughout the upper 300 m.

Acetone extracted measurements of Chl a ranged from 0.1
to 2.3 mg m⁻³ with the highest values generally in surface
waters (5–15 m). Surface Chl a was variable in the ICB, with
the lowest surface values (0.27–0.31 mg m⁻³) measured dur-
ing the first visit (Table 2). Peak Chl a values in the ICB
occurred on 10 April (2.2 mg m⁻³), after which Chl a de-
clined, reaching a low of 0.62 mg m⁻³ by the end of the
study (but remaining above initial Chl a values). Initial sur-
face Chl a values were higher in the NWB (0.58 mg m⁻³)
than the ICB, and generally increased throughout the cruise.
Figure 3. Seasonal variation in (a) satellite sea surface temperature (SST), (b) satellite daily incidental PAR, and day length and satellite Chl $a$ for (c) the ICB and (d) the NWB for 2012. The grey region indicates the period of the cruise. The vertical dotted lines in plots (c) and (d) indicate bloom initiation, calculated following Henson et al. (2009). The insets in (c) and (d) show the variation in satellite chlorophyll during the period of the cruise.

Table 1. Physicochemical features of the Iceland Basin and Norwegian Basin stations: Sta., station; SST, sea surface temperature; SSS, sea surface salinity; $C_T$, dissolved inorganic carbon; $\Omega_C$, calcite saturation state; $NO_3$, nitrate; $PO_4$, phosphate; $dSi$, silicic acid.

</table>

However, the magnitude of this increase was significantly smaller than in the ICB, peaking at only 0.93 mg m$^{-3}$. Euphotic zone integrated Chl $a$ showed a similar pattern to surface Chl $a$ across both stations, with the highest values on 10 April (ICB, 146.4 mg m$^{-3}$).

Satellite estimates of Chl $a$ also showed an increase in Chl $a$ at both sites during the cruise (Fig. 3c and d), although these values (< 0.4 mg m$^{-3}$) were much lower than measured in situ Chl $a$ (Table 2). The large increase in Chl $a$ associated with North Atlantic spring blooms occurred between 20 and 30 days after the cruise (Fig. 3c and d). Both sites were characterised by two peaks in Chl $a$ throughout the year: one in late spring (mid-June) and another in late summer (mid-August). The largest satellite-derived Chl $a$ values occurred in the ICB in late spring (1.7 mg m$^{-3}$, Fig. 3c), while in the

Figure 4. Surface (5–15 m) measurements of (a) particulate silicate (bSiO₂) and (b) diatom species abundance in the Iceland Basin. Black symbols indicate where diatoms were counted from Lugol’s samples, while open symbols indicate SEM counts.

Figure 5. Size-fractionated Chl a for (a, c) the Iceland Basin, and (b, d) the Norwegian Basin. Plots (a) and (b) show the < 10 and > 10 µm fractions, (c) and (d) show the < 2, 2–10, 10–20 and > 20 µm fractions.

Size-fractionated Chl a revealed very different communities at the two sites (Table 2 and Fig. 5). Initially in the ICB, approximately a quarter of the Chl a biomass was derived from the > 10 µm fraction (24–28%; Table 2, Fig. 5a). On subsequent visits, this increased significantly to 56–94% (Table 2, Fig. 5a). A general trend of an increasing contribution from the > 10 µm fraction was also observed in those samples collected for more detailed size fractionation (Fig. 5c). The detailed size fractionation showed that excluding the first ICB visit where samples were not collected, the > 10 µm fraction was completely dominated by the > 20 µm...
fraction in the ICB (Fig. 5c). Conversely, the > 10 µm fraction formed only a minor component (< 21 %) of the Chl a biomass in the NWB, although the > 10 µm contribution did increase throughout the cruise (Table 2, Fig. 5b). Detailed size fractionation in the NWB showed that the biggest increase in contribution came from the 2–10 µm fraction, increasing from 14 to 32 % (Fig. 5d), which was due to an increase in the absolute value of 2–10 µm Chl a (from 0.09 to 0.31 mg m⁻³).

3.3 Primary production

Primary production (PP) in surface waters (5–15 m) ranged from 0.41 to 4.89 mmol C m⁻³ d⁻¹ in this study (Table 2), with PP generally decreasing with depth. Surface PP correlated well with euphotic zone integrated PP (r = 0.98, p < 0.001, n = 7). The largest change in PP occurred in the ICB between 26 March and 10 April, when peak PP rates were observed in both the surface waters (4.89 mmol C m⁻³ d⁻¹) and integrated over the euphotic zone (221.9 mmol C m⁻² d⁻¹, Table 2). Following this peak, PP in the ICB declined, although it generally remained higher than pre-peak PP rates. The > 10 µm PP fraction contributed between 35 and 61 % of the total PP in the ICB. In contrast, the range and maximum rate of PP in the NWB was much lower than the ICB (0.67–1.11 mmol C m⁻³ d⁻¹, Table 2) with the > 10 µm PP making up a much smaller fraction (< 20 %). However, a clear increase in the > 10 µm PP fraction was observed between 14 April (5 %) and 25 April (20 %). The general trend in total and size-fractionated PP at both sites reflected that observed in the Chl a measurements.

3.4 Community structure

3.4.1 Community structure – picoplankton and nanoplanckton

Flow cytometry identified Synechococcus, autotrophic picoeukaryotes, and autotrophic nanoplanckton (< 10 µm) in relatively high abundance in all samples (Table 3). In general, Synechococcus and picoeukaryotes were more abundant in the NWB than the ICB. In the NWB, a contrasting pattern between Synechococcus, nanoplanckton, and picoeukaryotes was observed; while Synechococcus and the nanoplanckton increased significantly from 2617 to 5483 and 484 to 1384 cells mL⁻¹, respectively, a large decrease in picoeukaryotes was also observed, from 18 016 to 8456 cells mL⁻¹. A less coherent pattern was observed in the ICB, where peak concentrations of both Synechococcus (2112 cells mL⁻¹) and picoeukaryotes (6982 cells mL⁻¹) occurred on 19 April, with a general decline after this date.

3.4.2 Community structure – coccolithophores

The coccolithophore species identified by polarised light microscopy were Emiliania huxleyi, Coccolithus pelagicus, Calcidiscus leptoporus, Coronosphaera mediterranea, and Syracosphaera pulchra. More detailed SEM observations found a number of other species at low cell densities not clearly identified by the light microscope: Algirosphaera robusta, Acanthoica quattropinia, Calciopappus caudatus, Gephyrocapsa muellerae, Syracosphaera corolla, S. marginarorata, S. molischii, S. nodosa, S. ossa, and unidentified Syracosphaera spp. Many of these coccolithophore species have cell diameters between 10 and 20 µm, with the notable exceptions of E. huxleyi, G. muellerae, and the smaller Syracosphaera spp. (Young et al., 2003). Two morphotypes of E. huxleyi were observed in all samples (A and B) with morphotype A consistently dominant (71–100 % of total E. huxleyi numbers). The coccolithophore compositions at both sites were similar, with E. huxleyi generally the most abundant species (4.4–28.1 cells mL⁻¹, Table 3) at both sites, while C. was present in most samples at relatively low cell densities (0.15–2.79 cells mL⁻¹). The NWB was also characterised by the presence of A. robusta (2.7–12.7 cells mL⁻¹), while S. marginarorata (0–21.3 cells mL⁻¹) was only present in the ICB.

A general increase in coccolithophore abundance was observed in the ICB, with a large increase between 10 and 18 April (7.7–42.8 cells mL⁻¹). Emiliania huxleyi abundance decreased between 27 and 29 April (26.7–13.2 cells mL⁻¹), but C. pelagicus remained relatively constant (0.81–0.84 cells mL⁻¹). In the NWB, coccolithophores generally followed the trend of increasing Chl a with increases in abundance over time (Table 3). Within the coccolithophore communities, the largest relative increase in species abundance was by C. pelagicus with a sevenfold increase (0.38–2.66 cells mL⁻¹) between 14 and 22 April in the NWB.

3.4.3 Community structure – diatoms and microzooplankton

The diatom taxa identified by light microscopy were Chaetoceros, Cylindrotheca, Dactyliosolen, Guinardia, Leptocylindrus, Navicula, Pseudo-nitzschia, Rhizosolenia, Thalassionema, and Thalassiosira. Whilst samples for diatom counts were collected only once per visit to each station, particulate silicate (bSiO₂) samples were collected from two CTD casts per visit. As the major source of bSiO₂, the significant variability observed in bSiO₂ between the two CTD casts at each visit (Fig. 4a) suggested a temporal variability in the diatom cell abundance not captured in the Lugol’s counts. Therefore, diatom abundance counts were supplemented using SEM-image-based diatom counts from samples collected from those CTDs where Lugol’s samples were not collected (Fig. 4b). However, due to the relatively smaller volumes examined by SEM (~ 4.2 mL vs. 50 mL), there is a greater inherent error in the counts and as such Lugol’s counts were used wherever possible.
Table 3. Phytoplankton abundance at the Iceland Basin and Norwegian Basin stations, measured by flow cytometry (Synechococcus, picoeukaryotes, and nanoplankton), inverted microscopy (diatoms and microzooplankton), and polarising light microscopy (coccolithophores). Sta. stands for station.

</table>

The diatom community was highly variable in the ICB (Fig. 4). Initially present only in very low abundances (1.3 cells mL$^{-1}$, Table 3), a peak concentration of 249 cells mL$^{-1}$ was reached 15 days later on 10 April (day 101). The population then decreased over the rest of the study, down to 88 cells mL$^{-1}$, but remained above initial levels. A shift in composition was observed after the population peaked, from a Chaetoceros-dominated community (67–71 %) on 7 to 10 April (days 98 to 101) to one dominated by Pseudo-nitzschia (65–73 %, Fig. 4b) on 27 to 29 April (days 118 to 120). Diatoms were virtually absent from light microscope measurements of the NWB, reaching a maximum of only 0.5 cells mL$^{-1}$ (Table 3).

The main microzooplankton groups present were planktonic ciliates and small (~5–10 µm) naked dinoflagellates (e.g. Gymnodinium and Gymnomodium). Microzooplankton concentrations were ~4 times higher in the NWB (10.8–17.6 cells mL$^{-1}$, Table 3) than in the ICB (2.5–4.7 cells mL$^{-1}$, Table 3). Dinoflagellates initially dominated in the NWB (8.5 cells mL$^{-1}$), but were succeeded by ciliates (11.9–12.9 cells mL$^{-1}$). Both dinoflagellates and ciliates were present in similar concentrations in the ICB, except for the final visit, when dinoflagellates dominated (4.2 cells mL$^{-1}$).

4 Discussion

4.1 Time series or mixing?

The dynamic nature of the ocean causes inherent difficulties in interpreting data collected from fixed-point, Eulerian time series, such as those in this study. The distribution of phytoplankton in the ocean exhibits significant heterogeneity, which can be driven by mesoscale physical processes (Martin, 2005). Therefore, Eulerian time series are vulnerable to advection such that instead of repeatedly sampling the same phytoplankton community, each sample is potentially from a different population, possibly with a different composition. Before examining the development of the phytoplankton community, it is therefore necessary to consider the physicochemical environment. Eddies and other mesoscale features could potentially cause significant variations in measured SST, SSS, nutrients, and carbonate chemistry. With the possible exception of the nutrient concentrations, which are also affected by the biology present, the measured physicochemical parameters were stable throughout the study period (Table 1). Therefore, although we cannot rule out the influence of mesoscale features and advection during the study, the relative consistency of the sampled physicochemical environment suggests that the community structure is representative of the location, rather than from multiple eddies, and thus we can examine how the community developed during the cruise and compare between two geographically separated sites.

4.2 Drivers of the phytoplankton bloom

Density profiles in the ICB were seemingly indicative of a well-mixed water column (Fig. 2a), yet elevated fluorescence in the upper 100 m of the water column suggested that phytoplankton cells were not being evenly mixed throughout the water column (Fig. 2b). A detailed examination of the upper 100 m found small changes in the density profiles (Fig. 2a inset), corresponding to the elevated fluorescence, however the change in density with respect to depth was smaller ($\Delta \sigma < 0.025$ over 1 m) than most metrics used to identify mixed layers (e.g. Kara et al., 2000). Elevated fluorescence with only minimal stratification is consistent with the critical turbulence hypothesis (Huisman et al., 1999); here it is likely that active mixing had ceased, allowing phytoplankton net growth, while the response of the physical environ-
ment was slower than the biological response, and stratification was only just beginning to develop.

Although ICB upper water column fluorescence was elevated throughout the study, there was significant variation in the magnitude and structure of the fluorescence profiles (Figs. 3b and c), as well as a peak and decline in surface Chl \(a\) and primary production (PP). The general theory of bloom formation is that once conditions are favourable for bloom formation, the pre-bloom winter ecosystem will transition into a blooming ecosystem, identifiable by increasing Chl \(a\) biomass and PP. However, we did not observe this smooth transition. Instead, we observed periods of stability, characterised by increased stratification, Chl \(a\), and PP, followed by periods of instability where increased mixing weakened the developing stratification. Increased mixing detrains phytoplankton out of the surface waters, reducing both Chl \(a\) biomass and PP, and exporting them to depth (Giering et al., 2015). One such mixing event occurred between 27 and 29 April (days 118 and 120), where minor stratification \((\Delta \theta = 0.019)\) disappeared \((\Delta \theta < 0.001)\) over the upper 25 m, surface Chl \(a\) halved from 1.18 to 0.62 mg m\(^{-2}\), and the fluorescence profile became well-mixed (Fig. 2c). Furthermore, surface nutrients were replenished (Table 1). All of the above are indicative of a mixing event.

The transition period from winter to spring was also observed in satellite data from the ICB. Bloom metrics (Siegel et al., 2002; Henson et al., 2009) of satellite Chl \(a\) estimate that the main spring bloom did not begin until ∼20 days after our study period (dashed line in Fig. 3c). However, there was a significant increase \((r = 0.99, \ p < 0.015, \ n = 4)\) in Chl \(a\) during the study period (Fig. 3c inset), consistent with our in situ observations, that suggests that while the environment was not yet stable enough for sustained and rapid phytoplankton growth, intermittent net phytoplankton growth did occur. Therefore, we suggest that the early stages of a spring bloom are characterised by periods of instability and net growth, and that rather than a single smooth transition into a bloom, for a period of weeks prior to the main spring bloom event, phytoplankton form temporary mini-blooms during transient periods of stability. The export flux from these pre-bloom communities is a potentially significant food source to the mesopelagic (Giering et al., 2015). One such mixing event occurred between 27 and 29 April (days 118 and 120), where minor stratification \((\Delta \theta = 0.019)\) disappeared \((\Delta \theta < 0.001)\) over the upper 25 m, surface Chl \(a\) halved from 1.18 to 0.62 mg m\(^{-2}\), and the fluorescence profile became well-mixed (Fig. 2c). Furthermore, surface nutrients were replenished (Table 1). All of the above are indicative of a mixing event.

Besides physicochemical drivers of bloom formation, the plankton community itself can play a large role in the development and formation of a bloom. Physiological parameters such as net growth rates \(\left(\mu_{\text{Chl}}\right)\) and “assimilation efficiency” \(\left(\text{PP normalised to biomass, in this case Chl }a\right)\) can provide an insight into the state of the phytoplankton community. The NWB community had noticeably lower assimilation efficiency \((13.5–15.8 \text{ g C } [\text{g Chl }a]^{-1} \text{d}^{-1})\) than that in the ICB \((15.7–27.0 \text{ g C } [\text{g Chl }a]^{-1} \text{d}^{-1})\); thus, the relative increase in biomass in the NWB was slower, as reflected in the growth rates where the maximum estimated \(\left(\text{net}\right)\) growth rate in the NWB \(\left(\mu_{\text{Chl}} = 0.05 \text{d}^{-1}\right)\) was much lower than in the ICB \(\left(\mu_{\text{Chl}} = 0.22 \text{d}^{-1}\right)\). Assimilation efficiency varies with both environmental conditions and species composition, and therefore the composition of the phytoplankton community is likely to be another key driver behind the contrasting phytoplankton dynamics observed in the ICB and NWB.
4.3 Overall community composition

The contrasting structures of Chl $a$ and PP size fractions observed at the two sites (Fig. 5, Table 2) were reflected in the contrasting composition of the phytoplankton communities (Table 3). In the ICB, a change in dominance in both Chl $a$ and PP, from $<10$ to $>10\mu m$ fraction, occurred as the diatom abundance increased between 26 March and 7 April. An increase in the abundance of the $<10\mu m$ community was also observed during this period, composed mainly of $<2\mu m$ Synechococcus and picoeukaryotes (Table 3, Fig. 5c). However, most of the diatom population having cells $>20\mu m$ (Fig. 5c), their relatively large size allowed the diatoms to dominate both the Chl $a$ and PP while remaining numerically inferior. The decline in total Chl $a$ and PP later in our study was reflected by a decreasing abundance of most of the phytoplankton community (Table 3). However, the relative decrease of pico-phytoplankton (Synechococcus and picoeukaryotes) was greater than that of the diatoms, such that the $>10\mu m$ fraction increased its dominance for both Chl $a$ (94%) and PP (61%). Therefore, although surface Chl $a$ and PP declined after the “mini-bloom” event which peaked around 10 April, the community structure did not return to a pre-bloom composition, but instead remained dominated by diatoms.

Interestingly, the phytoplankton response to the increased diatom abundance was not uniform, with the nanoplanckton abundance decreasing and Synechococcus increasing only after the peak in diatom abundance. Thus, we observed that the phytoplankton community response during the spring bloom was not universal across functional types as has been previously observed elsewhere (Brown et al., 2008).

In contrast to the ICB, a large shift in the NWB community was not observed. Picoeukaryotes dominated both in terms of abundance (Table 3) and Chl $a$, through the $<2\mu m$ fraction (Fig. 5d). This is consistent with previous observations of early stage spring blooms (Joint et al., 1993). Although the $<2\mu m$ Chl $a$ fraction showed little variation throughout the study (0.45–0.58 mg m$^{-3}$), variation in the $<2\mu m$ phytoplankton composition did occur, with an apparent succession from picoeukaryotes to Synechococcus and nanoplanckton. This may represent a community shift early in development of the spring bloom or may demonstrate the inherent variability within pre-bloom communities.

The increase in total Chl $a$ in the NWB was driven primarily by the $2$ to $10\mu m$ fraction, which was likely composed of the nanoplanckton, which itself had a threefold increase in population size (from 484 to 1384 cells mL$^{-1}$, Table 3). The phytoplankton responsible for the observed increase in the $>10\mu m$ Chl $a$ and PP fraction cannot be confidently determined; large diatoms were absent and thus could not have contributed. The microzooplankton population consisted of ciliates and dinoflagellates (Gyrodiurn and Gymnodinium), both of which have been reported to be mixotrophic (Putt, 1990; Stoecker, 1999), and thus could potentially have contributed to the Chl $a$ measurements. Furthermore, it is possible that part of the nanoplanckton community, as measured by flow cytometry, was $>10\mu m$, and thus the increasing concentration of nanoplanckton could have also contributed to the increase in the $>10\mu m$ fraction.

4.4 Relative independence of the coccolithophore community

The traditional view on the seasonality of coccolithophores is that they succeed the diatom spring bloom, forming coccolithophore blooms in late summer. However, here we observed a typical North Atlantic community of coccolithophores (Savidge et al., 1995; Dale et al., 1999; Poulton et al., 2010), growing alongside the ICB diatom bloom, rather than just succeeding the diatoms. This is consistent with the rising tide hypothesis of Barber and Hiscock (2006), as well as observations from both in situ (Leblanc et al., 2009) and satellite measurements (Hopkins et al., 2015) suggesting that coccolithophores are present in North Atlantic spring blooms. Despite the contrasting environment and overall community structure of the NWB, the coccolithophore dynamics were similar, appearing independent of the overall community dynamics. Species-specific growth rates of coccolithophores (calculated from changes in cell concentration) found that E. huxleyi had the same net growth rate at both sites ($\mu = 0.06 d^{-1}$), while the net growth rate of C. pelagicus was comparable to E. huxleyi in the ICB, but was slightly higher in the NWB ($\mu = 0.13 d^{-1}$). Culture experiments of E. huxleyi and C. pelagicus have found comparable gross growth rates at temperatures below 10°C (Daniels et al., 2014), and our in situ observations support this conclusion. That C. pelagicus has higher net growth rates could also be indicative of higher grazing on the relatively smaller E. huxleyi (Daniels et al., 2014).

4.5 Contrasting patterns of diatoms

The diatom bloom in the ICB, which began between 26 March (day 86) and 7 April (day 98), was initially dominated by Chaetoceros (71–67 % of total cell numbers, Fig. 4b). As the community developed however, Pseudo-nitzschia succeeded as the dominant diatom genus (65–73 % of total). Both Chaetoceros and Pseudo-nitzschia are common spring bloom diatoms (Sieracki et al., 1993; Rees et al., 1999; Brown et al., 2003), with Chaetoceros often dominant in the earlier stages of North Atlantic spring blooms (Sieracki et al., 1993; Rees et al., 1999). Resting spores of Chaetoceros have also been observed to dominate the export flux out of the Iceland Basin during the North Atlantic spring bloom in May 2008 (Rynearson et al., 2013), suggesting dominance of the spring bloom prior to this period, consistent with the early community observed in our study. Pseudo-nitzschia (previously identified as Nitzschia in other studies) tends to dominate later in the spring bloom.
(Sieracki et al., 1993; Moore et al., 2005), also consistent with this study. This suggests that as a genus, Chaetoceros spp. are either able to adapt more quickly than Pseudo-nitzschia, or that they have a wider niche of growing conditions through a large diversity of species. However, once established, Pseudo-nitzschia spp. are able to outcompete Chaetoceros, resulting in a community shift. That the succession of the diatom community observed in the ICB is consistent with that expected in the main diatom spring bloom suggests that a mini-diatom bloom occurred prior to the formation of the main spring bloom.

The observed variability in the relationship between diatoms (the main source of bSiO$_2$) and bSiO$_2$ was likely due to the species-specific variability in the cellular bSiO$_2$ content of diatoms (Baines et al., 2010). The abundance of Pseudo-nitzschia, rather than Chaetoceros, best explained the trend in bSiO$_2$ ($r = 0.92$, $p < 0.001$, $n = 8$), suggesting that Pseudo-nitzschia was the major producer of bSiO$_2$. Previously, Chaetoceros has been observed as the major exporter of bSiO$_2$ in the Iceland Basin (Rynearson et al., 2013). Here, as the major producer of bSiO$_2$, Pseudo-nitzschia has the potential to also be the major exporter of bSiO$_2$.

In contrast to the ICB, diatoms appeared to be virtually absent ($< 0.5$ cells mL$^{-1}$) in the NWB. While the dSi : NO$_3$ ratio was below 1 : 1 requirement for diatoms, consistent with previous studies of North Atlantic blooms (Leblanc et al., 2009), dSi did not become depleted (always above 5 mmol Si m$^{-3}$, Table 1), and thus was not limiting. Furthermore, significant and increasing concentrations of particulate silicate (bSiO$_2$) were measured throughout the cruise (Fig. 4a). As the main source of bSiO$_2$, diatoms would therefore be expected to be present. Although absent in the Lugol’s counts, examination of SEM images found significant numbers (101–600 cells mL$^{-1}$) of small (< 5 μm) diatoms (predominantly Minidiscus spp.) that were too small to be identified by light microscopy. However, they may still constitute an important component of the nanoplankton, as measured by flow cytometry. As a result of their small cell size, nano-sized diatoms, such as Minidiscus, are easily missed when identifying and enumerating the phytoplankton community, and as such their potential biogeochemical importance may be greatly underestimated (Hinz et al., 2012). Other nano-sized diatom species have been observed as major components of the phytoplankton community on the Patagonian Shelf (Poulton et al., 2013), in the Scotia Sea (Hinz et al., 2012), the north-east Atlantic (Boyd and Newton, 1995; Savidge et al., 1995) and in the Norwegian Sea (Dale et al., 1999).

The Minidiscus spp. observed in this study exhibited a significant increase in population size during the study, from initial concentrations of 100 to 200 cells mL$^{-1}$, then up to 600 cells mL$^{-1}$ by the end of the study, and correlated well with both bSiO$_2$ ($r = 0.93$, $p < 0.01$, $n = 6$), and Chl a ($r = 0.93$, $p < 0.01$, $n = 6$). Furthermore, the increasing concentration of Minidiscus corresponded to the increase in the 2 to 10 μm Chl a size fraction (Fig. 5d). The maximum net growth rate of Minidiscus, estimated from changes in cell abundances ($μ = 0.13$ d$^{-1}$), was significantly higher than that calculated for the total community using Chl a ($μ_{Chl} = 0.05$ d$^{-1}$). While different methods were used to determine these growth rates, it does suggest that conditions were favourable for the small nano-sized diatoms to grow more rapidly than the bulk community.

The question therefore remains as to why the larger (> 10 μm) diatoms were virtually absent in an environment that is physically stable and nutrient replete, while small diatoms were able to thrive. The fate and ecology of overwintering oceanic diatoms is poorly understood. Many diatom species, both neritic and pelagic, are capable of forming resting stages that sink post-bloom (Smetacek, 1985; Rynearson et al., 2013), yet diatoms must be present in spring when the diatom bloom begins. Therefore, either a diatom population is sustained in the upper water column over winter (Backhaus et al., 2003), or the spring diatom community is sourced from elsewhere (horizontally or vertically). In relatively shallow coastal environments, benthic resting stages overwinter until spring when they are remixed up into the water column, providing the seed population for the spring bloom (McQuoid and Godhe, 2004). It is unlikely that oceanic diatom blooms are seeded from the sediment, as the depths are far too great for remixing. However, viable diatom cells have been observed suspended at depth (> 1000 m) in the ocean (Smetacek, 1985), and it is possible that these suspended deep populations are remixed to seed the spring bloom. An alternative hypothesis is based on the observation that diatom blooms generally occur first in coastal waters before progressing to the open ocean (Smetacek, 1985), suggesting that coastal diatom populations are horizontally advected into pelagic waters, thus seeding the spring bloom in the open ocean from shelf waters. The location of the source coastal populations, and their transit time to the open ocean location, would then affect the timing of the diatom blooms.

With such low concentrations of > 10 μm diatoms (< 0.5 cells mL$^{-1}$) in the NWB, it is possible that the overwintering diatom population was too small to seed the spring bloom. Grazing pressure by microzooplankton and mesozooplankton may influence the composition and timing of the onset of the spring bloom (Behrenfeld and Boss, 2014). The potential grazing pressure from the significant microzooplankton population (10.8–17.6 cells mL$^{-1}$) in the NWB may have exerted such a control on the observed diatom population that it could not develop into a diatom bloom. Instead, an alternative seed population of diatoms may be required to overcome the grazing pressure and initiate the diatom bloom in the NWB. Whether the absence of large diatoms is a regular occurrence in the NWB, or whether inter-annual shifts between small and large diatoms occur, as observed in the north-east Atlantic (Boyd and Newton, 1995), will have significant implications for export and the functioning of the biological carbon pump. The absence of larger diatoms in
pelagic spring blooms in the Norwegian Sea has also been observed by Dale et al. (1999), and it may be that large diatoms are completely absent from the pelagic south-east Norwegian Sea. The lack of large diatoms in the NWB could explain the seasonal profile of satellite Chl a (Fig. 3d); with no large diatoms present, the spring bloom is less intense, peaking at only 60% of the Chl a concentration found in the ICB.

Clearly, further work is required to examine why large diatoms are absent from the initial stages of the spring bloom in the NWB, and whether they ever become abundant in this region.

5 Conclusions

During March–May 2012, satellite and in situ data from study sites in the Iceland Basin (ICB) and the Norwegian Basin (NWB) suggested that despite very different physical environments, the two sites both represented early stages in the development of the North Atlantic spring bloom. Spring bloom initiation in the ICB was limited by the physical environment, with periods of increased mixing inhibiting bloom formation. The physicochemical environment alone did not limit bloom formation in the NWB as, in spite of a stable stratified water column and ample nutrients, Chl a biomass and primary production were relatively low. Phytoplankton efficiency (Chl a-normalised primary production) was also lower in the NWB, suggesting that the phytoplankton community composition and/or physiology was also a limiting factor in bloom formation.

The phytoplankton community in the NWB was dominated by the < 2 µm Chl a fraction, with high concentrations of picoeukaryotes (∼ 18 000 cells mL⁻¹) succeeded by Synechococcus and nanoplanктон. In contrast, although the initial dominance of the < 10 µm Chl a fraction (picoeukaryotes and nanoplanктон) was succeeded by diatoms dominating in the > 10 µm Chl a fraction, the ICB phytoplankton community generally followed the rising tide hypothesis, with most of the community positively responding to the onset of the diatom bloom. Interestingly, coccolithophore dynamics were similar at both sites, independent of the overall community, with similar concentrations of the main species Emiliania huxleyi and Coccolithus pelagicus.

In terms of the diatom community, Chaetoceros initially dominated the ICB diatom bloom, but was replaced by Pseudo-nitzschia as the bloom progressed, suggesting Chaetoceros as a key species in diatom bloom formation, while Pseudo-nitzschia was the major source of particulate silicate (bSiO₂). The lack of large (> 10 µm) bloom-forming diatoms in the NWB, while small (< 5 µm) diatoms were present in high numbers (101–600 cells mL⁻¹), suggests that microzooplankton grazing, coupled with a potential lack of a seed population, restricted diatom growth in the NWB, or that large diatoms are absent in NWB spring blooms.

These results suggest that despite both phytoplankton communities being in the early stage of bloom formation and exhibiting positive net growth rates, different physicochemical and biological factors control bloom formation with the resulting blooms likely to be significantly different in terms of biogeochemistry and trophic interactions throughout the growth season. Clearly, more in situ studies are needed in the transitional period between winter and the peak productivity of the spring bloom to examine compositional differences, growth and mortality factors, and how regional variability impacts on upper ocean biogeochemistry and deep-sea fluxes of organic material. Coupled studies of satellite-derived products, including bloom phenology and phytoplankton physiology, and in situ processes are needed to examine the full spectrum of factors forming the spring bloom.
