Abstract
The coordination of multiple Unmanned Aerial Vehicles (UAVs) to carry out surveys is a major challenge for emergency responders. In particular, UAVs have to fly over kilometre-scale areas while trying to discover casualties as quickly as possible. However, an increase in the availability of real-time data about a disaster from sources such as crowd reports or satellites presents a valuable source of information to drive the planning of UAV flight paths over a space in order to discover people who are in danger. Nevertheless challenges remain when planning over the very large action spaces that result. To this end, we introduce the survivor discovery problem and present as our solution, the first example of a factored coordinated Monte Carlo tree search algorithm to perform decentralised path planning for multiple coordinated UAVs. Our evaluation against standard benchmarks show that our algorithm, Co-MCTS, is able to find more casualties faster than standard approaches by 10% or more on simulations with real-world data from the 2010 Haiti earthquake.

Introduction
The increased prevalence of low-cost, robust, commercially available Unmanned Aerial Vehicles (UAVs) has led to concerted efforts to utilise these platforms in disaster response. Specifically, UAVs have seen widespread use in recent disasters—such as the 2010 Haiti earthquake and the 2015 Nepal earthquake—aiding first responders with collecting imagery and other sensory data without putting human lives at risk (Adams and Friedland 2012; Goda et al. 2015; Meier 2015). In particular, an important body of work has focused on developing UAVs that act as autonomous systems to minimise the involvement of overstretched first responders; both to conserve valuable manpower and to ensure their safety (Crisis Mappers 2013; Murphy 2012; United Nations Foundation 2011). Key to this work, is the idea of enabling coordinated UAVs to explore a disaster space to discover the spatial location of casualties: a difficult task given the extent and large number of possible locations to visit.

To enable this exploration, advances in data collection—and specifically crowd-sourcing (Morrow et al. 2011; Goodchild and Glennon 2010)—have created new sources of information about disaster scenarios that contribute to increased awareness of the situation on the ground during a disaster. Such information is vital given the size and scale of the effects of natural disasters (Fowler 2016). For instance, during 2010 a magnitude 7.3 earthquake struck Haiti near the capital, Port-Au-Prince, which caused widespread destruction over thirty kilometres from the epicentre and resulted in the destruction or damage of over three hundred thousand homes; the death or injury of over five hundred and twenty thousand people; and around one point three million displaced persons needing temporary shelter (Government of the Republic of Haiti 2014). A natural extension of the use of UAVs in these events is to fully exploit prior data on the extent and nature of the disaster (whether crowd-sourced or otherwise) in order to maximise the likelihood of rescuing or discovering casualties quickly. However, at present there is no specific work that seeks to use spatial information on the distribution of people and the expected danger—for instance the likely rate of fatalities due to structural damage to buildings or from the spread of radiation—to inform the paths of UAVs through a disaster space, in order to maximise the number of observations made of possible casualties.

Currently, the state of the art for UAV path planning algorithms focuses on three main areas, the first of which is target tracking for surveillance (Bernardini, Fox, and Long 2014; Hu et al. 2014; Kolling and Kleiner 2013). Now, although these techniques are related to the exploration of a disaster space, they are designed to find a known number of targets that are in motion, rather than an unknown number of survivors distributed over an area. Other developments in path planning focus on trying to reach a set goal location (or state) (Chen et al. 2014; Durkota and Komenda 2013; He 2007; Kothari, Postlethwaite, and Gu 2009) or working with single autonomous UAVs (Cashmore et al. 2014; Kothari and Postlethwaite 2012); neither of which fulfill the need for algorithms that coordinate multiple vehicles in an explorative traversal of the disaster space, rather than aiming for a particular final location. Specific challenges exist in coordinating multiple vehicles. For example, there is often no benefit to multiple UAVs providing imagery of the same location: there must be coordination between the vehicles to allow them to find survivors in a disaster, without all attending the same locations.

In line with the terminology used in this field (Bry and Roy (2011), Gan and Sukkarieh (2011), Waharte, Trigoni, and Julier (2009) and others) we henceforth refer to data
distributed over a spatial representation of a disaster area as a belief map. This belief map can come from different sources, including crowd-sourcing, but we assume it has the characteristics of mapping spatial locations onto some function that represents numerical data: for instance number of people or radiation levels.

Our work seeks to address these challenges with the following three contributions:

1. We introduce a formulation of the survivor discovery problem, informed by several datasets collected following natural disasters;
2. We develop a decentralised algorithm that allows multiple UAVs to coordinate the exploration of a large disaster space with many states;
3. We test and evaluate our approach on real-world data simulating a very large action space, showing consistent gains in survivor discovery of over 10% compared to benchmarks.

The rest of the paper is organised as follows. First we discuss the background of using UAVs in disaster response and the types of problems that existing research has focussed on; next we describe the specifics of the problem we seek to solve by formulating the survivor discovery problem; we then detail our use of a coordinated Monte-Carlo tree-search algorithm (including examples); before showing the benefits of our implementation with three experimental scenarios using real-world datasets; and finally summarising our work and proposing an extension of the algorithm and a removal of some assumptions.

**Background**

In order to best use UAVs to aid responders in disasters they must be able to plan paths autonomously, as a group. Furthermore, as we have already indicated, it is beneficial to use prior information about the area to inform the flight paths of UAVs in order to maximise the likelihood of discovering survivors. Currently, work on path planning in robotics focusses primarily on reaching goal locations and frequently formulates path planning as a control problem (Goerzen, Kong, and Mettler 2009). Conversely, in a disaster scenario there need not be any final end-point to a UAV’s path planning; rather the length of the exploration may be constrained by—for example—battery life, and the number of people to be discovered must be maximised over the length of the path. Alternatively, much work has also been done to enable the use of vision algorithms and belief data to track mobile targets or map an area (Liu and Dai 2010). However, this area of research often focusses on locating a known number of targets, or covering a bounded space for the purposes of mapping. In contrast, the task of searching for casualties in disaster response can be summarised as the localisation of an unknown number of people as quickly as possible (Fawcett and Oliveira 2000; Chiu et al. 2002), in order to ensure quick rescue or attention by emergency services and thus the greatest chance of survival (Macintyre, Barbera, and Petinaux 2011). Consequently techniques for known numbers of targets or for mapping environments are not useful.

Against this background, we find closer similarities with work on solving Markov Decision Processes (MDPs); specifically where locality of UAVs can be used to reduce calculation overheads. In particular, the generality of the MDP formulation lends itself well to the construction of a simulation environment given numerical data used for a belief map, as well as having a number of well-established solutions. Specifically, work by Amato and Oliehoek (2015) utilises factored tree-searches for partially observable MDP solutions, and demonstrates performance benefits over state of the art un-factored solver POMCP (Silver and Veness 2010). This performance advantage is obtained by exploiting problem structure to allow factorisation in a way reflective of local state spaces and interactions. In a similar way, we use factored trees in this paper to represent the available actions of UAVs in a disaster environment, factoring the value of locating people between UAVs within spatial proximity of each other. Notably—because of the dimensions of the physical area we consider—we deal with a very large state-space, which must be particularly carefully sampled since complete searches are computationally intractable. We also include—for the first time—real data from a disaster scenario to validate our model.

We next introduce the specific formulation of the problem we tackle, and explain the origin of the large state-space.

**The Survivor Discovery Problem**

In this section to formulate the problem of finding a number of survivors in a disaster-area, with a team of cooperative UAVs planning their actions and coordinating with each other if required, in order to maximise the number of people discovered. All of this is to be done in the presence of a model of the danger to the casualties expressed as an estimated fatality rate mapped to spatial locations. As such the problem is one of prioritising visits to areas of high expected numbers of people, while also attending areas with high expected fatality rates as quickly as possible. We now describe; in turn; the environment model, the behaviour of UAVs in the simulation, and the specific problem of discovering survivors. Following this we introduce the Bellman equation (used to characterise MDPs) for our scenario.

**Environment Model**

We begin by discretising the search-space to allow for fast plan creation. Specifically, we formulate the survivor discovery problem as exploring a uniform $x \times y$ sized grid world—$C$—formed of cells, each cell $c_{ij}$ contains an unknown number of people, $p_{ij} \in \mathbb{Z}^*$, and a scalar value $d_{ij} \in [0, 1]$ denoting the danger in the cell as the probability of any person in the cell dying during the next time step. Time steps are denoted by an integer value $t \in \mathbb{Z}^*$, with subsequent steps referred to by adding integer values; for example $t + 1$. If a value depends on time, this is denoted in parentheses; i.e. $p_{ij}(t)$.

$\text{Cells are indexed for their horizontal and vertical position respectively by } i,j.$
UAV Behaviour Formulation

The area $C$ is explored by the set of UAVs $U = \{u_1, \ldots, u_m\}$ that traverse $C$ from cell to cell once per timestep. Each UAV is equipped with sensors capable of accurately detecting people inside one cell at any given timestep: i.e. they return the value of $p_{ij}$ deterministically (this is a simplifying assumption we will address in further work). Each UAV, $u_k$, must select its own trajectory $T_k \subseteq C$ with contiguous borders, through the area, forming the set of all UAV trajectories $T = \{T_1, \ldots, T_m\}$. To address double-counting the values in each cell, we introduce the union of all the trajectories in the set $T$ as $\mathcal{T}(T) = \bigcup_{T_k \in T} T_k$. Additionally, we impose constraints on the length of each UAV’s planned trajectory to account for limits on battery life. If the maximum number of cells that can be traversed due to the battery limitations of a UAV $u_k$ is denoted $b_k \in \mathbb{Z}^+$, then the maximum trajectory length is simply $|T_k| \leq b_k \forall k \in \{1, \ldots, m\}$, which we denote $\bar{f}$.

The action vectors enabling the UAVs to transition from cell to cell are defined as $a_k = (\leftarrow, \rightarrow, \uparrow, \downarrow)$ for each UAV $u_k$, (each arrow representing the direction of motion: we do not consider the UAVs remaining stationary as according to our model this can never result in more reward than moving). We impose the constraint that the available actions are restricted to UAVs at the edge of the grid world (i.e. explicitly where the UAV occupies a cell $c_{ij}$ where $i = 0$ or $x$, or $j = 0$ or $y$) so that they do not have the action available to cross out of the grid area. At any given time, the vector denoting all possible UAV actions is given by $a = (a_1, \ldots, a_m)$, and represents all possible combinations of movements available to all UAVs. The set of all actions available to all UAVs at any arbitrary time forms the total action space $A$, which we now incorporate into the standard Bellman equation.

Exploration Problem Formulation

Having described the environment and UAV behaviour, we formulate the multi-UAV exploration problem as a Markov Decision Process (MDP), comprising a tuple $(S, A, R, P)$ of states $S$, actions $A$, rewards $R$, and transition probabilities $P$, which we define below. Since the UAVs are not aware in advance of the ground-truth values of $p_{ij}$ and $d_{ij}$ in each cell, computations are instead made using prior belief-data about the expected number of people $\bar{p}_{ij} \in \mathbb{R}^*$ and the expectation value of the probability of death $\bar{d}_{ij} \in [0, 1]$ of each person in a cell in a given time step. We also consider a binary variable $v_{ij} \in \{0, 1\}$ denoting the visibility of the cell: i.e. whether it has been observed by a UAV. This allows us to construct the tuple $s_{ij}$ to denote the state of a cell $c_{ij}$:

$$s_{ij} = \langle \bar{p}_{ij}, \bar{d}_{ij}, v_{ij} \rangle$$

The set of these for all cells in $C$ forms the global state variable $s = \{s_{00}, \ldots, s_{xy}\}$. With this constructed, we next formulate an update procedure for the expected value of the number of people in a given cell after a time step $t$ by computing the product of the current expected number of people and the probability of survival:

$$\tilde{p}_{ij}(t + 1) = \tilde{p}_{ij}(t)(1 - \tilde{d}_{ij})$$

Here, $\tilde{d}_{ij}$ for the next time step is dependent on whether a cell has been observed. If so, we consider the danger to reduce to zero, since first responders are now be aware of the need to rescue the people occupying that cell:

$$\tilde{d}_{ij}(t + 1) = \begin{cases} 0 & \text{if } v_{ij}(t) = 1 \\ \tilde{d}_{ij}(t) & \text{otherwise} \end{cases}$$

This assumption need not hold in general. However, it is a convenient way of indicating that no further utility can be derived from revisiting a cell once it has been observed. In a scenario with trapped survivors it is reasonable to assume there will be no large-scale movement of population during the search. Indeed, in many cases victims are often recovered after being trapped in the same location for days at a time (Macintyre, Barbera, and Petinaux 2011).

We note the logical extension of equation 2 to times at an arbitrary point in the future $t'$, as required for planning future actions:

$$\tilde{p}_{ij}(t') = \tilde{p}_{ij}(t)(1 - \tilde{d}_{ij})^{t' - t}$$

We record the set of positions of each UAV $u_k \in U$ at time $t$ as $g_k(t) \in C$, which we denote as members of the vector of all UAV positions:

$$g(t) = \langle g_1(t), \ldots, g_m(t) \rangle$$

where the indices on each $g$ correspond to the indices of the UAV at that location. Additionally, we record the set of unique UAV locations as the union of the elements of $g$ as:

$$G(t) = \bigcup_{k=1}^{m} \{g_k(t)\}$$

Thus, the state of the map at a time $t$ is a tuple comprising the state of each cell, and the position of each UAV: $\vec{s}(t) = \langle \vec{s}(t), g(t) \rangle$.

As a result, we formulate the immediate reward to all UAVs at timestep $t$ as a function of the expected number of people saved due to UAV observation. Specifically, this is the product of the expected number of people in a cell multiplied by the death rate in that cell, summed over all unique cells where a UAV is present (i.e. all members of the set $G$):

$$R(t) = \sum_{G(t)} \tilde{p}_{ij}(t) \times \tilde{d}_{ij}$$

Over an infinite time horizon, we consider the sum of expected rewards for each time step:

$$\sum_{t=0}^{\infty} R(t) = \sum_{t=0}^{\infty} \sum_{c_{ij} \in G(t)} \tilde{p}_{ij}(t) \times \tilde{d}_{ij}$$

Since $G$ is itself dependent on the trajectory of each UAV (i.e. the cell each UAV occupies at any time $t$) this can be said to be equivalent to:

$$\sum_{t=0}^{\infty} R(t) = \sum_{c_{ij} \in \mathcal{T}(T)} \tilde{p}_{ij}(t) \times \tilde{d}_{ij}$$
Thus, \( R \) must be maximised over the trajectory of all UAVs in order to observe (and subsequently ‘save’) the maximum number of people. The key challenge is to allow the path planning to be coordinated between UAVs to maximise global, rather than local, reward (shown explicitly by the inclusion of \( G \) in Equation 1). We briefly discuss the implications of the UAVs detecting \( p_{ij} \) with certainty, and justify this assumption, at the end of this section.

**Bellman Equation**

Having formulated the environment, the UAVs, and the discovery problem; we finally formulate the standard MDP Bellman optimality equation, where we denote \( R \)’s dependence on the actions and state space (which themselves depend on \( t \)):

\[
Q(a, s) = R(a, s) + \sum_{s'} P(s' | a, s) \max_{a'} Q(a', s')
\]

In our case, we do not require the diminishing-returns term \( \gamma \) to ensure \( Q(a, s) \) is finite, since the diminishing value of examining a cell further in the future is expressed in the reduction of the expected number of people as a result of the death-rate term (see Equation 2). We incorporate this in the reward function. In other words, \( Q(a, s) \) cannot exceed the number of people alive in the space, given \( s \).

We also do not require the explicit sum over various states since the transition probability \( P \) between states given a fixed action is (as discussed below) deterministic. While this simplifies the form of the action value function, we still require the result be optimal according to:

\[
Q(a, s) = R(a, s) + \max_{a'} Q'(a', s')
\]

from which we obtain the optimal action: \( a = \arg \max_a Q \). To maximise current and future reward. While ostensibly a simplification of a typical MDP formulation, the problem is far from trivial as the joint action space \( a \) at any time step grows as an exponent of the number \( m \) of UAVs in the system, namely: \( |a| \propto a_k^m \), while the possible combinations of \( G \) grow proportional to:

\[
| C | = (x \times y)!
\]

i.e. a combinatorial function of the dimensions of the environment. The result is a state space \( S \) of extremely large size (we give a specific example in our Results section below) even before accounting for the permutations of \( p, d, \) and \( v \).

We now briefly discuss the implications of the discoveries in the environment happening deterministically and how this does not affect our planning.

**Determinism in our Model**

With regards to the rewards obtained in our formulation, we note here the implications of determinism of detection of people in our model. Whilst the construction above relies on expected values of reward for exploration of a cell—since we cannot in advance know the true conditions on the ground (implied above in the unknown quantities \( p_{ij} \) and \( d_{ij} \)) — we can still consider our MDP model deterministic, with the following justification. All planning in our decision making processes can only rely on the expected value of cell reward. Once a cell has been visited, and the true reward discovered, further exploration of the cell in our model yields no further reward (see below). Furthermore, at this stage we do not consider correlation between adjacent cells. This is because we ensure the decomposition results in cells encompassing entire buildings that in Haiti—and in Port au Prince in particular—are often built sporadically and have little relation to the structures in their surroundings (Government of the Republic of Haiti 2014). As a result, planning is not affected upon discovery of the true reward of visiting a cell, and we can therefore consider the prediction of future expected reward deterministic. Having clarified this point, we now introduce our solution to the survivor discovery problem in the environment model just described.

**The Coordinated Monte Carlo Tree-Search Algorithm**

Our decision to base our algorithm on Monte-Carlo tree search (MCTS) methods is due to their ability to sample very quickly from large state spaces (traditionally used in solving games), and the flexibility with which they can be applied to general problems (including MDPs) (Browne et al. 2012; Amato and Oliehoek 2015). This former point is particularly vital in our scenario as we have already noted the extremely large number of configurations possible in the environment (Equation 5). The principal purpose of our algorithm is to allow UAVs to use MCTS algorithms to calculate coordinated paths without incurring the cost described in Equation 5. To do this we exploit locality between UAVs to factor the search space into local joint-action trees. Furthermore, we allow trees to coordinate over shared factors (that is, shared UAVs). To this end we use the max-sum algorithm (Ramchurn et al. 2010; Rogers et al. 2011) as we note its ability to guarantee neighbourhood maximal rewards, and can do so in relatively few iterations (Farinelli, Rogers, and Jennings 2014).

Specifically, we introduce an additional step to the standard MCTS process of tree growth. This growth is typically summarised: node selection, expansion, rollout or simulation, and backpropagation (Browne et al. 2012; Kocsis and Szepesvari 2006). However, in our case we need to allow the UAVs to search their future actions whilst also accounting for the actions of other UAVs and the impact they will have on the reward obtained (that is, on the survivors discovered). Most significantly, we modify the selection process to determine which node to expand by coordinating in parallel between trees via max-sum: resulting in an exploration algorithm factored between multiple subsets of UAVs. This represents the first time a factored tree-search has been applied to a UAV search simulation. We detail our approach in the following subsections.

**Tree Construction**

At each timestep in the simulation, the coordinated MCTS (Co-MCTS) algorithm begins by calculating which UAVs
require coordination with their neighbours, leading to the form of the UAV-based factor graph constructed in the joint-action creation function $J$ (Line 3). This is performed to establish whether coordination is needed in a given UAV’s locality. In cases where a UAV is spatially isolated from neighbouring UAVs, a local tree is grown. The resulting groups of UAVs will form the basis of the factor graph used in the max-sum calculation (Line 14 in Algorithm 1). The result of $J$ is represented formally by a set $N = \{n_1, \ldots, n_f\}$ that represents the domain of the factor nodes to be coordinated. Specifically, each member of $N$ contains a set of actions corresponding to a group of UAVs that require coordination.

In more detail, for some set of neighbouring UAVs—for example $\{u_1, u_2, \ldots, u_k\}$—the possibility exists of $g_1(t + 1) = g_2(t + 1) = \ldots = g_k(t + 1)$ at the next time step $t + 1$ of a simulation. In this case, the corresponding element in $N$—say $n_i$—would be the set of actions available to these UAVs: $n_i = \{a_1, a_2, \ldots, a_k\}$. Notice that since a UAV may interact (that is, potentially occupy the same cell at a future timestep, and thus form a joint tree) with more than one neighbour, the condition $\bigcap_{n_k \in N} n_k = G$ must hold, whereas $\bigcap_{n_k \in N} n_k = \emptyset$ will, in general, not. Trees are grown for each $n_i$ in $N$, each of which in turn represents the factors in the max-sum graph connected to the variables representing the available actions of the UAVs. Individual nodes in the tree $n_i$ will be indicated as $n_i^{(k)}$ or from any arbitrary tree by $n_k$.

Having described the construction of the trees, we now detail how each tree is grown in order to sample from the action space.

**Tree Growth**

Algorithm 1 begins with the creation of the root nodes representative of each factor seen in Line 6, which are recorded in the set $N_r$ (Line 4). Following this, the creation and growth of branches is performed $\Delta$ times inside the loop beginning at Line 9. This begins by exploring down each tree, starting from the root node, to determine which node to branch on next. Similarly to standard upper confidence bound MCTS (Kocsis and Szepesvari 2006), this begins by selecting nodes which have hitherto not been fully expanded: that is, there remain neighbouring action states that have not yet been branched to previously. The total number of neighbouring actions $\nu$ from a given action node is of order $\nu = \prod_{a_{\beta} \in n_\alpha} |a_{\beta}|$ for a tree corresponding to factor node $n_\alpha$, simplifying to $\nu = |a_{\beta}|^{n_\alpha}$ when all UAVs in the set have the same number of available actions. Thus, the operation of the function in Line 18:

$$\text{fullexp}(n^{(k)}) = \begin{cases} 
\text{True} & \text{if } e = \nu \\
\text{False} & \text{otherwise}
\end{cases}$$

where $e$ is the number of previous expansions of that node. Line 10 introduces the current set of nodes (across all trees) to be expanded next, $N_{\text{next}}$, and Line 11 creates the set of previously expanded nodes $N_{\text{prev}}$. At Line 14 the max-sum algorithm is used to maximise the value of the actions over each $n_i$, returning a vector of favourable actions $a^* = (a_1^*, a_2^*, \ldots, a_m^* \mid a_k^* \in a_k)$. Since each $n_i$ depends on a subset of actions, the function $\text{select}(n^{(k)}, a^*)$ serves to return only the actions corresponding to a given $n^{(k)}$. This is then used as the argument to create the new expansion to a node in $N_{\text{next}}$ in Line 17.

34. endfor

An example factor graph and trees are shown in Figure 1, for four interacting UAVs. Their actions are shared between two factor graph utility nodes, hence the two joint action trees $n_1$ and $n_2$. Four expansions of the root are shown where the action of the shared UAV—$u_3$—has been coordinated between the trees each time, thus ensuring contradictory actions are not chosen for the same UAV in two different trees. A second depth of growth is shown in Figure 2, where coordination has resulted in a newly created node with common action for $a_3$ of $\uparrow$.

**Rollout**

The rollout portion of the MCTS is traditionally a coarse estimate of the affect of future actions as the result of explor-
Figure 1: Example factor graph and the first iteration of tree growth for four interacting UAVs. Here $u_3$ can interact with any of the other UAVs, and is thus common to the two joint-action trees, which coordinate in order to maximise the reward from its actions in conjunction with the other UAVs. Factor and utility nodes are synonymous with variable and function nodes as outlined in (Ramchurn et al. 2010).

Figure 2: New nodes created at lower depth in the tree, where the actions of $u_3$ have again been coordinated to be ↑ in both cases.

Figure 3: Danger as a function of position, created from Ushahidi dataset centred over Port-au-Prince

The number of unique sets of UAV positions $G$ (that is, the cardinality of the state space) in this environment for (for example) five UAVs, is of the order $8.5 \times 10^{20}$ (referring to Equation 5); even without the variation in the expected number of people with time. Using this environment, we measure performance by evaluating the number of survivors averaged over each UAV over each timestep. That is:

$$f \cdot \sum_{m} f_{m} \sum_{c_{ij} \in G(t)} \bar{p}_{ij}(t)$$

where $f$ denotes the final time step (a stopping time introduced simply as a limit of the simulation), and we recall that $m$ is the total number of UAVs, and $G(t)$ is the unique positions of the UAVs at time step $t$.

Figure 4 shows our results for an initial test of the coordinated Monte Carlo tree search using randomised starting locations for four simulated UAVs. We compare against, a simple “lawnmower” sweep search—a typical strategy employed in search and rescue situations (Goodrich et al.

200 × 200 of 10m cells, with UAVs traversing from the centre of one cell to the centre of an adjoining cell above, below, or to either side at each time step. This is convenient since assuming a UAV speed—typical of quad rotor vehicles—of 10m/s$^{-1}$ amounts to the traversal of one cell in one timestep of one second.

Damaged buildings represent an estimate of the damage in an area and thus, the danger to the victims on the ground: buildings that have suffered more severe damage will likely lead to more severe casualties and a higher rate of death. We formed a belief map of danger to the populace by summing the total number of buildings above a threshold level (set to a crowd report of damage 3 and above) in each cell, before multiplying by a common factor to convert the data into a map representative of expected fatalities (noting the constraint in Equation 1). The environment is displayed in Figure 3 with a scale showing the value of $d$ in each location.

Results

To verify the performance of our algorithm on data relevant to real-world disaster scenarios, we used data from the Ushahidi project (Morrow et al. 2011) produced from crowd-sourced information during the 2010 Haiti earthquake. Specifically, we extracted the level of damage and coordinates of buildings in a 2km square centred on the capital, Port-au-Prince. Damage was rated based on crowd reports on a scale from 1 to 5, with 5 being the most severe.

We then constructed a decomposed grid world of size

$200 \times 200$ of 10m cells, with UAVs traversing from the centre of one cell to the centre of an adjoining cell above, below, or to either side at each time step. This is convenient since assuming a UAV speed—typical of quad rotor vehicles—of 10m/s$^{-1}$ amounts to the traversal of one cell in one timestep of one second.

Damaged buildings represent an estimate of the damage in an area and thus, the danger to the victims on the ground: buildings that have suffered more severe damage will likely lead to more severe casualties and a higher rate of death. We formed a belief map of danger to the populace by summing the total number of buildings above a threshold level (set to a crowd report of damage 3 and above) in each cell, before multiplying by a common factor to convert the data into a map representative of expected fatalities (noting the constraint in Equation 1). The environment is displayed in Figure 3 with a scale showing the value of $d$ in each location.

Figure 3: Danger as a function of position, created from Ushahidi dataset centred over Port-au-Prince

The number of unique sets of UAV positions $G$ (that is, the cardinality of the state space) in this environment for (for example) five UAVs, is of the order $8.5 \times 10^{20}$ (referring to Equation 5); even without the variation in the expected number of people with time. Using this environment, we measure performance by evaluating the number of survivors averaged over each UAV over each timestep. That is:

$$f \cdot \sum_{m} f_{m} \sum_{c_{ij} \in G(t)} \bar{p}_{ij}(t)$$

where $f$ denotes the final time step (a stopping time introduced simply as a limit of the simulation), and we recall that $m$ is the total number of UAVs, and $G(t)$ is the unique positions of the UAVs at time step $t$.

Figure 4 shows our results for an initial test of the coordinated Monte Carlo tree search using randomised starting locations for four simulated UAVs. We compare against, a simple “lawnmower” sweep search—a typical strategy employed in search and rescue situations (Goodrich et al.

$^5$Available from http://www.ushahidi.com/
as well as a typical MCTS algorithm (as per the work of Chaslot et al. (2008)) without the factored coordination we introduce. We also demonstrate explicitly the forward planning required in the survivor discovery problem, by benchmarking against Co-MCTS without a rollout policy, and a greedy (but locally coordinated via max-sum) policy. Results demonstrate a minimum performance increase of 10% over MCTS, and higher gains over the other benchmarks. Errors are taken as standard error of the mean over 1000 repeats of each experiment. The poor performance of a greedy one-step lookahead shows that even with coordination, the ability to forward-plan to account for survivor death rates is essential to discovering casualties in our scenario. Indeed, simple un-planned lawnmower-style sweep searches are more successful, but still fall short of the MCTS’s ability to plan exploration paths to target (for instance) high-danger areas before casualty rates become too high.

Additionally, we explicitly demonstrate the benefit of the consistency afforded by our coordination in a simulation. We do this by varying the number of UAVs present and comparing to the closest benchmark to Co-MCTS’s performance from our initial simulation. Good coordination should benefit the overall reward gained by the algorithm (in our case the number of people rescued) with low diminishing returns compared to uncoordinated approaches. Specifically, any additional UAVs should still find close-to the same number of casualties as other UAVs in the system, if they coordinate the exploration task effectively as a group. If they do not, one would expect additional UAVs would explore the same regions of the disaster space as those already present: which, as discussed previously, offers no benefit to the global reward function. This is demonstrated in Figure 5 for varying \( m \), where we note performance improvements of 12% with the inclusion of 6 UAVs (and an average of 6% across the experiment). This is notable after 3 UAVs are introduced, since before this point interaction (and therefore required coordination between the UAVs) was at a minimum since the search space was large enough to accommodate multiple non-intersecting explorative paths. For more UAVs, coordination is more commonplace and with the successful implementation of Co-MCTS there is higher value in the inclusion of further UAVs into the scenario, compared to a situation without coordination.

Figure 4: Comparison of performance between: coordinated MCTS, un-coordinated MCTS, simple lawnmower sweep search, Co-MCTS with no rollout policy, greedy policy with max-sum coordination. Start locations were uniformly randomised, \( m = 4 \), \( f = 1000 \).

Figure 5: Comparison of coordinated and un-coordinated MCTS in locating survivors with additional UAVs; demonstrating a consistent performance per-UAV in Co-MCTS. Initial UAV starting locations fixed at \( c_{0,0} = [0,0] \); \( f = 1000 \).

Figure 6: Comparison of coordinated and un-coordinated MCTS in locating survivors over varying densities of population, showing Co-MCTS’s consistency in different forms of belief data. Here \( c_{0,0} = [0,0] \); \( f = 1000 \); and \( m = 5 \).

Finally, we demonstrate how Co-MCTS performs consistently in varying environments. For the algorithm to be viable, it should show performance benefits in a variety of situations with a variety of distributions of casualties to be discovered. We achieve this by varying the relative population over the belief-space from 1 (as above), down to 0.25 by uniformly sampling from the Ushahidi dataset to the population portion of the belief map. This has the effect of maintaining our standard of using real data with a large action space, while still allowing us to experiment over different state spaces (\( S \)). The results presented in Figure 6 demonstrate this consistency with an average 14% improvement over the un-coordinated MCTS benchmark: even at low densities of people; where the coordination requirements would
be intuitively less valuable. We thus provide evidence that the performance gains of Co-MCTS are not simply a by-product of the test environment selected.

Conclusions
Motivated by the recent increased availability of belief-data about disaster environments, we have introduced an implementation of a decentralised, factored, coordinated Monte Carlo tree search algorithm for the purpose of discovering survivors in a simulated UAV path planning scenario. Tests were carried out on real-world data from the 2010 Haiti earthquake via the Ushahidi platform; an environment with a very large (of order $8.5 \times 10^{20}$) action space. We demonstrated the capability of our Co-MCTS algorithm in sampling this space and planning paths, and demonstrated consistent performance gains in the number of survivors discovered of $> 10\%$. Future work will seek to extend these solutions to time-varying belief maps to cope with the situation in which data is collected and updated during exploration, and removing the assumption of a cellular disaster area to tackle the issue of discretising (and therefore potentially oversimplifying) the data collected.
