48 **Abstract**

49 Histone methyltransferases (HMTs) are important epigenetic regulators of gene transcription and
50 are disrupted at the genomic level in a spectrum of human tumors including hematological
51 malignancies. Using high-resolution SNP-arrays, we identified recurrent deletions of the *SETD2* locus
52 in 3% (8/261) of chronic lymphocytic leukemia (CLL) patients. Further validation in two independent
53 cohorts showed that *SETD2* deletions were associated with loss of *TP53*, genomic complexity and
54 chromothripsis. With next generation sequencing we detected mutations of *SETD2* in an additional
55 3.8% of patients (23/602). In most cases, *SETD2*-deletions or mutations were often observed as a
56 clonal event and always as a mono-allelic lesion, leading to reduced mRNA expression in *SETD2*-
57 disrupted cases. Patients with *SETD2* abnormalities and wild-type *TP53* and *ATM* from five clinical
58 trials employing chemotherapy or chemo-immunotherapy, had reduced progression-free and overall
59 survival compared to cases wild-type for all three genes. Consistent with its postulated role as a
60 tumor suppressor, our data highlights *SETD2* aberration as a recurrent, early loss-of-function event
61 in CLL pathobiology linked to aggressive disease.

62

63 **Introduction**

64 The transfer of methyl groups from S-adenosyl methionine to lysine or arginine residues on histone
65 proteins, catalyzed by histone methyltransferases (HMTs), is an important regulator of gene
66 transcription. Accordingly, HMTs are disrupted by various mechanisms including chromosomal
67 translocations, genomic loss and/or point mutations in both solid and hematological malignancies.¹
68 Among the increasing number of HMT aberrations identified in human malignancies, recurrent loss
69 and/or inactivating mutations of the tumor suppressor gene *SETD2*, were initially identified in clear
70 cell renal cell carcinoma (ccRCC)² and subsequently in other solid tumors e.g. high grade gliomas.³
71 Moreover, *SETD2* mutations have been reported in a subset of patients with acute lymphoblastic
72 leukemia⁴ and acute myeloid leukemia, especially those with rearrangements in the another HMT
73 gene, *MLL*.⁵ *SETD2* is the only enzyme that catalyzes the trimethylation of lysine 36 on histone 3
74 (H3K36me3), one of the major chromatin marks associated with active transcription. Recent studies
75 have linked *SETD2* to the maintenance of genomic integrity, through coordination of homologous
76 recombination repair after double strand breaks. The loss of *SETD2* impairs DNA repair and enhances
77 genomic instability, supporting its tumor suppressor role.⁶⁻⁹

78 Chronic lymphocytic leukemia (CLL) is characterized by remarkable clinical heterogeneity such that
79 some patients pursue an indolent course while others require early treatment. Considerable effort
80 has focused on understanding the genetic diversity that underpins this clinical heterogeneity. High-
81 resolution genomic arrays and next-generation sequencing have identified recurring novel regions of
82 genomic copy-number aberrations (CNAs) like del(13q), del(11q), trisomy 12 and del(17p) and
83 recurrent driver mutations in genes such as *TP53*, *ATM*, *SF3B1* and *NOTCH1*, respectively (reviewed
84 in¹⁰). Mutations frequently involve genes encoding proteins with important roles in cell signalling,
85 cell cycle control, DNA repair and RNA-splicing and processing; however the reported incidence of
86 mutations in chromatin modifiers is lower than in many other haematological malignancies.

87 In this study, we report the identification of recurrent deletions and mutations of the *SETD2* gene in
88 large, well-characterized CLL cohorts. *SETD2* lesions appear to represent early events in CLL
89 pathogenesis, often co-existing with, but preceding *TP53* abnormalities. They are associated with
90 genomic complexity and chromothripsis, and identify a subgroup of patients with poor outcome.

91 **Methods**

92 Patients

93 We studied samples taken from 1006 CLL patients either at entry into one of five clinical trials or
94 from a cohort of untreated patients with progressive disease managed at the Royal Bournemouth
95 Hospital. Four randomized trials (ADMIRE, ARCTIC, UK CLL4¹¹, GCSG CLL8¹²) compared chemo or
96 chemo-immunotherapy regimens in fit previously untreated patients while the fifth trial (SCSG
97 CLL20) enrolled ultra-high risk patients who were either refractory to a purine analogue or were
98 previously untreated with a 17p deletion. Further details of the clinical trials are provided in **Table S1**.
99 All patients were diagnosed using standard morphologic and immunophenotypic criteria. Informed
100 consent was obtained from all patients in accordance with the Helsinki declaration, and this study
101 was approved by national or regional research ethics committees.

102 Patients were grouped into three cohorts (discovery [n=261], extension [n=635] and ultra high-risk
103 [n=110]); details of the cohort composition and *SETD2* analysis are summarised in **Table 1**,
104 **Supplementary methods** and **Supplementary figure 1**. DNA was extracted from CLL B cell samples
105 (all with >80% tumour purity) and from matched germ-line DNA for *SETD2*-mutated cases as
106 outlined in **Supplementary methods**. The assessment of established biomarkers was performed as
107 previously described.¹³ 572 and 602 samples were screened for *SETD2* loss and mutation,
108 respectively, with 168 cases screened for both loss and mutation.

109 Genome-wide microarray-based copy number analysis

110 DNA from 261 discovery and 110 ultra-high risk cases was amplified, labelled and hybridized to the
111 Affymetrix SNP6.0 platform, aligned onto the human genome sequence (GRCh37) and analysed in
112 Partek Genomics Suite (Partek Inc, Missouri, USA) as reported previously.¹⁴⁻¹⁸ DNA from 201 pre-
113 treatment extension cases (ADMIRE and ARCTIC) was hybridized to the Illumina HumanOmni1-Quad
114 and HumanOmniS-8 platforms according to manufacturer's protocols.^{19,20} Further experimental
115 details are provides in the **Supplementary methods**.

116 Targeted re-sequencing and whole exome sequencing

117 93 CLL samples from the discovery cohort (and five matched germ-line controls) were processed and
118 analysed for mutations in *SETD2* (all exons) and a number of clinically relevant genes with a bespoke
119 Haloplex Target Enrichment system (Agilent Technologies) (**Supplementary Methods Table 1**) and
120 processed and analysed as previously reported.²¹ An additional 231 cases from our pre-treatment
121 extension cohort were screened for *SETD2* mutations using a TruSeq Custom Amplicon panel

122 (Illumina Inc. San Diego, CA, USA) as previously described.^{20,22} All the variants identified by both
123 platforms were annotated against dbSNP (build 135) and functional prediction was also performed
124 using SIFT and Polyphen2 analysis. Somatically-acquired *SETD2* mutations (n=4) were also identified
125 in the recent whole exome sequencing (WES) study of 278 matched tumor and germ-line cases from
126 the GCGG CLL8 study.²³ Additional experimental details are provided in the **Supplementary methods**.

127 Sanger validation

128 Variants in *SETD2* were subjected to validation by conventional Sanger-based sequencing of PCR
129 products obtained from tumor [n=11] and where possible, paired normal genomic DNA [n=5]. The
130 expression of *SETD2* mutations at mRNA level was also tested in samples with available material
131 [n=4]. Primers for DNA or mRNA validation are listed in **Table S2**.

132 Quantitative RT-PCR

133 Total RNA was isolated from purified CLL cells of 36 patient samples using RNeasy columns (Qiagen)
134 and reversed transcribed using the Improm™II RT-PCR kit (Promega, UK) according to the
135 manufacturer's instruction. Primers and probes for the housekeeping genes (18s) and target genes
136 (*CCDC12*, *NBEAL2*, *KIF9*, *KLHL18*, *SETD2*) were selected using the Universal Probe Library (Roche
137 Applied Science, UK) (**Table S3**). Two independent assays were designed to ascertain expression of 3'
138 and 5' *SETD2*. Normal B-cell mRNA was used to normalize the expression of each gene by delta-delta
139 CT method as previously described.²⁴

140 Statistical analysis

141 Statistical analysis was performed with SPSS v22. Differences between samples were analysed by U-
142 Mann Whitney test. Progression-free survival (PFS) and overall survival (OS) were calculated for
143 clinical trial samples from randomization. Survival analysis was performed by Kaplan-Meier and log-
144 rank analysis. Significant differences were considered with P-values lower than 0.05.

145

146 **Results**

147 Recurrent deletions of 3p are a feature of CLL

148 We identified 1024 acquired CNAs (mean 3.9, range 0–45) in our discovery cohort (**Table S4**).
149 Deletions of chromosome 3p [del(3p)] were observed in 8 patients (3%), ranged from 0.45–81 Mb in
150 size (**Table S5**), and identified a well delineated MDR between genomic location 46.96–47.39 Mb,
151 containing the genes *CCDC12*, *NBEAL2*, *SETD2*, *KIF9* and *KLHL18* (**Figure 1A**). We compared the
152 expression of these genes by qRT-PCR in 3p deleted [n=6] versus non-3p deleted patients [n=8]
153 (**Figure 1C**). We were not able to detect the expression of *KIF9* mRNA in CLL or normal B-cells.
154 Within the MDR, the HMT gene *SETD2* was significantly under-expressed, measuring by two
155 different assays targeting the 3' or 5' region of the mRNA (p<0.0001 for both assays).

156 We then aimed to confirm the presence of 3p deletions and refine the MDR in our extension cohorts.
157 Firstly, we identified nine del(3p) cases (4.5%) in our extension pre-treatment cohort, permitting the
158 MDR to be refined to the *SETD2* and *KIF9* loci (47.12–47.36 Mb, **Figure 1A** and **Table S5**). Across our
159 discovery and pre-treatment extension cohorts, *SETD2* deletions were present in 17/461 cases
160 (3.7%), significantly associated with deletions and/or mutations of *TP53* (p=0.003) and genomic
161 complexity (≥3 deletions²⁵, p=0.04) (**Figure 1B**). GISTIC 2.0 analysis²⁶, an algorithm for identifying
162 statistically significant regions of CNA above an estimated background rate (FDR q-value <0.25),
163 showed that in 39 *TP53* deleted cases (del(3p), n=15), the *SETD2* region on 3p21.31, was deleted at a
164 significant frequency (q-value=0.001), ranked third after del(13q) and del(17p) (**Figure S2**).

165 Interestingly, *SETD2* deletions without concomitant *TP53/ATM* abnormalities [n=6] also exhibited
166 significantly more genomic complexity than wildtype patients (p=0.01. **Figure 1D**). Two *SETD2*-
167 deleted cases showed evidence of chromosome 3 chromothripsis (based on >10 CNAs per
168 chromosome¹⁸) (**Figure 1A-B**). In the ultra-high risk cohort, *SETD2*-deletions were detected in 9% of
169 cases [10/110], and were significantly enriched compared to the pre-treatment cohort (p=0.009). All
170 ten had loss of *TP53* and five had concomitant chromosome 3 chromothripsis (**Figure 1B**). To further
171 establish the significance of our *SETD2* deletion in cases with chromosome 3 chromothripsis, we
172 mapped all recurrently 3p deletions in these cases. This analysis showed that whilst additional
173 regions of recurrent deletion were observed on 3p, the only regions shared across all patients
174 included the *SETD2* locus (**Table S6**).

175 We analysed *SETD2* expression in an extended cohort of patients with 3p deletions [n=16], and again
176 the expression was diminished in these patients compared to wild-type patients (P=0.0068; **Figure**
177 **S3**). In order to study the clonal nature of the *SETD2* deletions, we assigned each genomic CNA with

178 a relative copy-number value by normalizing CNA intensity values from array features. We excluded
179 regions with gain and sex chromosome CNAs from the analysis. The cut off for normal copy number
180 was established between 1.7 and 2.3. We could infer that the 3p deletion was in the dominant clonal
181 population in 11/18 (61%) cases with data available for analysis (**Figure S4**).

182 *SETD2* mutations in CLL

183 To identify somatic gene mutations, we initially employed targeted re-sequencing of 93 discovery
184 cohort cases and identified 122 non-silent mutations (non-synonymous n=80, frameshift indel n=20,
185 splicing n=9, nonframeshift indel n=6, stopgain n=6, stoploss n=1) targeting 37 genes in 71/93 cases
186 (mean 1.8, range 1-4). Sanger sequencing confirmed 93.6% of the tested variants [n=79], whilst the
187 remaining unconfirmed variants were present at low read depth (n=3) or in a low percentage of
188 mutant reads (n=2). We found *ATM* [n=14], *TP53* [n=14], *NOTCH1* [n=20] and *SF3B1* [n=15]
189 mutations at a frequency expected for the studied cohort, which aligns with published data and
190 demonstrates the validity of the re-sequencing platform. We identified non-synonymous *SETD2*
191 mutations in four (4.3%) discovery cases (p.D99G, p.Q1545K, p.W1306*, p.E1955Q) (**Figure 2A-B**).
192 Sanger sequencing validated that all of the *SETD2* mutations were present in tumor DNA. We
193 obtained matched germ-line DNA from three patients and confirmed that the mutations were
194 somatically acquired (p.D99G, p.W1306*, p.E1955Q) (**Figure S5A**).

195 To corroborate this preliminary observation, we investigated 231 cases of our pre-treatment
196 extension cohort by TruSeq amplicon-based sequencing. We identified an additional nine (3.9%)
197 *SETD2* mutations (p.A50T, p.L89F, p.P167L, p.N53S, p.E670K, p.M1742L, p.M1889T (x2), p.I2295M)
198 (**Figure 2A-B**). Sanger sequencing confirmed each *SETD2* variant in the tumour material and in two
199 cases with germ-line material available, the variants were somatically acquired. Assessment of WES
200 data of the CLL8 study²³ samples included in our pre-treatment extension cohort, revealed the
201 presence of somatically-acquired *SETD2* mutations in 4/278 cases (1.4%), namely,
202 p.EEEELQSQQ1919fs, p.L1804fs, p.VLEYC1576del, p.V1190M. None of these *SETD2* mutations (**Table**
203 **2**) are annotated in COSMIC²⁷. During the preparation of this manuscript, a study performed by
204 Puente et al. in 506 CLL patients also described both *SETD2* mutations (0.8% of cases) and deletions
205 in 3p (2% of cases) whose MDR encompassed *SETD2*²⁸ whilst Landau et al identified *SETD2*
206 mutations in 8/538 (1.5%) cases²³.

207 In total, across our cohorts there were 15 somatically-acquired *SETD2* variants (15/602; 2.5%). An
208 additional eight variants that could not be examined in germ-line material were either absent (n=3),
209 reported to have a very low prevalence (n=5) in 1000 Genomes project or have a sub-clonal variant
210 allele frequency (%VAF <0.45, (n=1); **Table 2**). Therefore, whilst these eight variants are predicted to

211 be functionally deleterious, we cannot exclude that the minority may be rare germ-line variants as
212 they exhibit clonal variant allele frequencies in the tumor material.

213 We were able to confirm the expression of the *SETD2* mutations at mRNA level in four of our
214 patients with available material (p.D99G, p.Q1545K, p.E1955Q, p.E670K) (**Figure S5A**), and qRT-PCR
215 analysis of three *SETD2* mutated samples showed that *SETD2* mRNA expression was reduced
216 compared to wild-type patients (P=0.035; **Figure S3**).

217 We performed integrative analysis of 93 cases from our discovery cohort with Haloplex re-
218 sequencing and SNP6.0 copy number data available, by employing the ABSOLUTE algorithm.²⁹ This
219 approach estimates the cancer cell fraction (CCF) harboring a given mutation by correcting for
220 sample purity and local copy number changes. Mutations were classified as clonal if the CCF
221 was >0.95 with a probability >0.5, and sub-clonal otherwise.³⁰ In additional cases with proven-
222 somatic *SETD2* mutations (n=4) and paired copy number data from our pre-treatment validation
223 cohorts, we performed this estimation by manually correcting for tumor sample purity and local
224 copy-number. Our analysis demonstrated the expected sub-clonal distribution of established gene
225 mutations, such as *TP53*, *ATM*, *SF3B1* and *NOTCH1*. Interestingly, all our somatically acquired *SETD2*
226 mutations exhibited a clonal CCF, suggesting that these mutations may be early events in the
227 evolution of CLL (**Figure 2C-D & Figure S5B-C**), although further studies are required to confirm this
228 observation.

229 *SETD2* aberrations are associated with inferior progression free- and overall survival

230 Finally, we analysed the impact of *SETD2* abnormalities (deletion or somatically-acquired mutation)
231 on progression-free (PFS) and overall survival (OS) in front-line trial patients. We observed a
232 significantly shorter PFS in cases with *SETD2* abnormalities that were wild-type for *TP53/ATM* [n=7],
233 compared to cases wild-type for *TP53/ATM/SETD2* [n=62] (PFS: 30 vs. 48 months; p=0.003) (**Figure**
234 **2E**). The same patients with *SETD2* abnormalities [n=7] also had a shorter OS than wild-type patients
235 [n=62] (OS: 34 vs. 92 months; p<0.001) (**Figure 2F**). Whilst these data suggest that *SETD2* aberration
236 may be clinically relevant, further investigation in larger cohorts is needed to understand their full
237 impact on survival.

238

239 **Discussion**

240 This study was based on an initial high-resolution SNP6.0 array analysis of 261 untreated patients
241 with progressive CLL which identified a recurrent deletion of the short arm of chromosome 3 in 3%
242 of cases (n=8). The MDR included the *CCDC12*, *NBEAL2*, *SETD2*, *KIF9* and *KLHL18* genes, of which
243 *SETD2* was the most significantly under-expressed in tumor cells. We then identified clonal,
244 somatically-acquired *SETD2* mutations in 4.3% of this cohort; no mutated case had a concomitant
245 *SETD2* deletion.

246 The *SETD2* gene encodes a 230 kDa protein that is non-redundantly responsible for all trimethylation
247 of lysine 36 on histone H3 (H3K36me3),^{31,32} a mark that is associated with actively transcribed
248 regions and is involved in transcriptional elongation and splicing.³³ In addition, recent studies have
249 linked this epigenetic histone mark to other important cellular processes such as the regulation of
250 mismatch repair, efficient homologous recombination and the maintenance of genomic stability.⁷⁻⁹
251 *In vitro* inhibition of Setd2 decreases global levels of H3K36me3 and impairs the recruitment of the
252 mismatch recognition protein hMutS α onto chromatin, thereby preventing appropriate DNA
253 mismatch repair. Cells lacking the Setd2 protein display microsatellite instability and have elevated
254 levels of spontaneous mutations.^{7,34-36} Inactivating *SETD2* mutations were first described in ccRCC^{2,6},
255 subsequently in other solid tumors such as paediatric high-grade gliomas and most recently in a
256 subset of patients with acute lymphoid and myeloid leukemias.^{2,5,37,38} *SETD2* mutations in ccRCC are
257 frequently associated with 3p deletions resulting in loss of both *SETD2* and VHL genes, while in acute
258 leukemias, *SETD2* mutations may be bi-allelic but 3p loss is rare. *SETD2* genomic abnormalities are
259 associated with decreased H3K36me3 levels, a distinctive DNA methylation signature⁶ and
260 chemoresistance in paediatric acute lymphoblastic leukemia³⁹. In MLL-rearranged cells from acute
261 leukemic patients, Setd2 knockdown is implicated in disease initiation and progression by promoting
262 the self-renewal capacity of leukemic stem cells.

263 In view of the role of *SETD2* disruption in tumorigenesis and the identification of *SETD2*
264 abnormalities in our discovery cohort, we then accrued samples from other patient cohorts,
265 including the GCLLSG CLL8 cohort in which 3p deletions had also been detected¹⁸, to confirm the
266 incidence of *SETD2* disruption and evaluate its biological and clinical consequences in CLL. Previously
267 untreated patients sampled at randomization to chemo or chemo-immunotherapy trials had a
268 similar incidence of 3p deletions (4.5%) to that seen in the discovery cohort while a higher incidence
269 of loss (9%) was found in the ultra-high risk cohort. The inclusion of additional cohorts enabled a
270 smaller MDR to be defined, including *SETD2* and *KIF9*, implicating *SETD2* as the key deleted gene.
271 The incidence of *SETD2* mutations was comparable in all cohorts tested, no synonymous mutations

272 were identified and when germ-line material was tested, all mutations were somatically acquired.
273 The diverse sequencing strategies utilized in this current study precluded the application of
274 computational tools like MutSigCV⁴⁰, an algorithm that identifies significantly mutated genes by
275 accounting for background mutation rate, DNA replication time and the gene size. However, we did
276 assess the *SETD2* background mutation rate, expression level and replication timing data from
277 Lawrence et al⁴⁰ demonstrating that *SETD2* shares no properties associated with false-positive
278 candidate cancer genes (**Figure S7**). The recent studies by Puente *et al* and Landau *et al*, published
279 during the preparation of this manuscript confirms the rare but recurrent nature of *SETD2*
280 abnormalities^{23,28}. *SETD2* deletions were not over-represented by analysis of WES generated copy
281 number data in the work by Landau and the mutation frequencies of both studies were lower than
282 those in our study. The different frequencies reported in these two studies could be explained by
283 cohort composition, as our study included ultra-high risk CLL and patients randomized to clinical
284 trials.

285 As we found *SETD2* mRNA expression to be down regulated in cases with either *SETD2* deletion or
286 mutations and as we did not observe bi-allelic *SETD2* abnormalities, we assessed whether *SETD2*
287 may also be deregulated by DNA methylation. Kulis and co-workers⁴¹ reported no differential
288 methylation levels in the *SETD2* gene body and promoter regions (15 and 9 CpG probes), respectively
289 between unmutated or mutated CLL or major cytogenetic sub-types and *SETD2* mRNA expression
290 was not correlated with gene methylation status [doi:10.1038/ng.2443: Supplementary tables 5 &
291 11]⁴¹. Preliminary analysis of our own unpublished Illumina 450K methylation array data also
292 demonstrated no differences between mutated and unmutated CLL for these probes (**Figure S6**). In
293 addition, when we analysed *SETD2* expression in a published CLL dataset
294 (<http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE2466>)⁴⁴ using the Oncomine portal
295 (<https://www.oncomine.org>),⁴² we observed a heterogeneous pattern. Reduced levels are evident in
296 the minority of patients, which given our observed association between *SETD2* deletion and
297 expression could imply gene deletion in those Oncomine samples with low mRNA expression.
298 Together, this suggests that DNA methylation does not play a substantial role in regulating *SETD2*
299 expression in B-CLL cells, as previously noted in acute leukemia⁵.

300 Across all cohorts, *SETD2* deletion was found in both *IGHV* mutated and unmutated cases but was
301 strongly associated with *TP53* loss and mutation, likely accounting for its higher incidence in the
302 ultra -high risk cohort. We also noted an association with genomic complexity even in cases lacking a
303 *TP53* or *ATM* abnormality, consistent with the role of *SETD2* in maintaining genomic stability.
304 Moreover, we identify several *SETD2* deletions that appeared to be the result of chromothripsis. The
305 somatically-acquired *SETD2* mutations showed a comparable genomic distribution to those

306 previously described in other tumors and were predicted to have deleterious functional
307 consequences. Furthermore, their association with significantly reduced mRNA expression in those
308 cases analysed, suggest that they either directly affect mRNA expression, or co-exist with other
309 defects in transcriptional control at this locus. Interestingly, we did not observe a statistically
310 significant association between *SETD2* mutations and *TP53* abnormalities or genomic complexity, the
311 implication of which may be differing functional consequences of mono-allelic loss and mutation.

312 In our study, both *SETD2* deletions and mutations often appeared to be clonal and may precede
313 *TP53* abnormalities in at least some cases. *Setd2* has been shown to directly regulate the
314 transcription of a subset of genes via cooperation with the transcription factor p53,⁴³ and the link
315 between *SETD2* and *TP53* is an interesting association worthy of functional validation. It is possible
316 that the *SETD2* alterations present in our CLL cases may contribute to further inactivation of p53-
317 mediated checkpoint control, a situation that has been proposed in ccRCC.⁸ The low frequency of
318 *SETD2* disruption and the association with *TP53* abnormalities hinder an accurate assessment of its
319 clinical consequences. Nevertheless, we observed a shorter PFS and OS in patients with *SETD2* but
320 no *TP53* or *ATM* abnormalities compared to cases wild type for all three genes. In support of this
321 preliminary clinical observation, it has been shown that 3p deletions in head and neck squamous
322 carcinoma (HNSCC) are associated with reduced survival.⁴⁴ Furthermore, the authors showed that
323 the co-existence of a *TP53* abnormality with del(3p) decreased survival further, an observation that
324 we could not confirm in our cohort.

325 In summary, our current study provides the first comprehensive analysis of CNAs and mutations
326 targeting the *SETD2* gene in a large cohort of patients with CLL. We find somatic deletions and
327 mutations in ~7% of CLL patients requiring treatment. These associate with *TP53* dysfunction,
328 genomic complexity and chromothripsis and may be early clonal events. Functional studies are now
329 warranted to elucidate the exact biological importance of *SETD2* in CLL pathogenesis, but our data
330 adds to a growing body of evidence suggesting a role for H3K36me3 in tumorigenesis that may be
331 exploited for the development of novel therapeutic approaches.

332 Acknowledgements

333 The authors gratefully acknowledge all patients who contributed to this study. This work was funded
334 by Bloodwise (11052, 12036), the Kay Kendall Leukaemia Fund (873), Cancer Research UK
335 (C34999/A18087, ECMC C24563/A15581), Wessex Medical Research and the Bournemouth
336 Leukaemia Fund. SS is supported by the Else Kröner-Fresenius-Stiftung (2012_A146), and Deutsche
337 Forschungsgemeinschaft (SFB 1074 projects B1, B2). The LRF CLL4 trial was funded by a core grant

338 from Leukaemia and Lymphoma Research. D.G. and D.C. acknowledge the support by The Royal
339 Marsden Hospital and The Institute of Cancer Research National Institute of Health Research
340 Biomedical Research Center. RR is supported by the Swedish Cancer Society, the Swedish Research
341 Council, Science for Life Laboratory, Uppsala University, Uppsala University Hospital, and the Lion's
342 Cancer Research Foundation, Uppsala.

476

477 **Figure Legends**

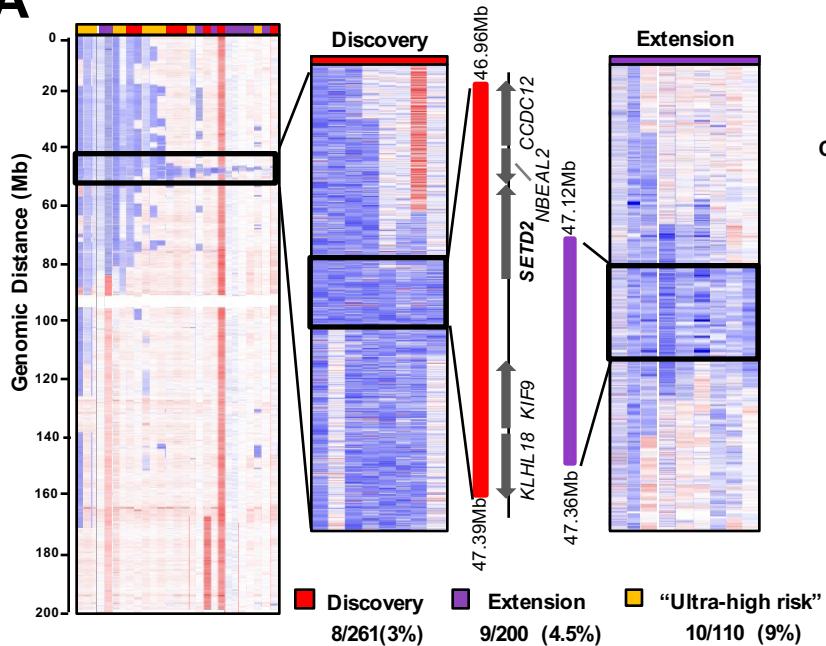

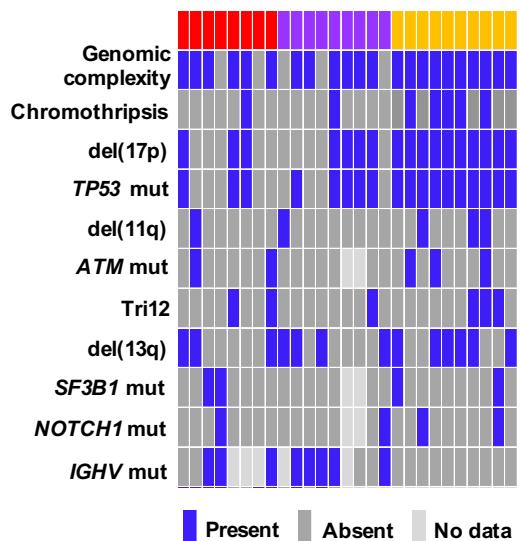

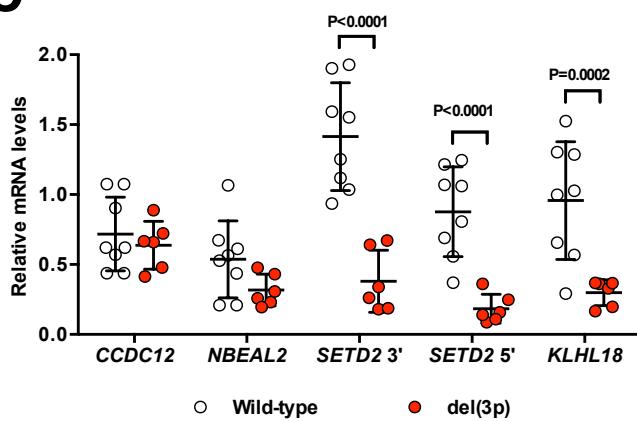

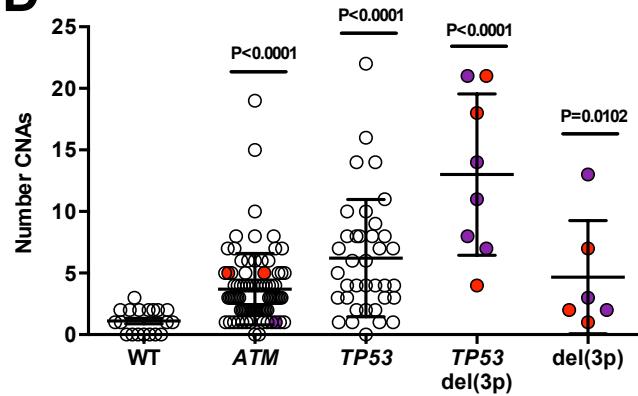

478 Figure 1. SETD2 deletions in our discovery, extension and ultra-high risk cohorts

479 **Figure 1A.** SNP6.0 data for the del(3p) cases. Genomic location is indicated by the ladder to the left.
480 Each column represents one patient. Loss, gain and normal copy-number are shown as blue, red and
481 white, respectively. The black box indicates the MDR, and is displayed in greater detail for our
482 discovery and extension cohorts. The genes in the MDR with their transcriptional direction are
483 displayed in the middle, with the MDR from the discovery and extension cohorts shown by the red
484 and purple bars, respectively. **1B.** Matrix displaying the biomarkers and genomic features associated
485 with del(3p) cases with the discovery, extension and ultra-high risk cases shown in red, purple and
486 yellow, respectively. **1C.** Real-time PCR expression for the five genes localized in the discovery MDR
487 in cases with or without del(3p). All the samples were negative for KIF9. 18s was employed as
488 housekeeping gene. Expression in normal B-cells was used as a normalization sample. Mean ± SD is
489 represented. **1D.** Scatterplots displaying the number of CNA observed in subgroups of our cohort
490 (excluding ultra-high risk cases). Cases were assigned to a subgroup using a hierarchical model;
491 presence of del(17p) and/or TP53 mutation, then del(11q) and/or ATM mutation, then del(3p) cases
492 with and without TP53 abnormalities and then wild-type (WT) cases containing no del(17p), del(11q),
493 del(3p) or mutations in ATM and TP53. Mean ± SD is represented.

494 Figure 2. SETD2 mutations in our discovery and extension cohorts

495 **Figure 2A.** Schematic diagram of the Setd2 protein with their key functional domains. Mutations are
496 displayed on the diagram. The colour denotes the cohort, and the filled circles are mutations that
497 have been confirmed as somatically acquired. **2B.** Matrix displaying the biomarkers and genomic
498 features associated with SETD2 mutated cases in the discovery (red) and extension (purple) cases. **2C.**
499 Analysis of the clonality for SETD2 and other recurrently mutated genes on CLL. For each case the
500 cancer cell fraction (CCF) is derived manually or with the ABSOLUTE algorithm. Only somatically
501 acquired validated mutations are displayed (cases 69, 100, S21 and 88). The number of mutations (n)
502 for each gene in the analysis is shown (bottom). **2D.** Percentage of cases harboring clonal or
503 subclonal mutations for each of the genes displayed. **2E.** Kaplan-Meier and log-rank analysis for
504 progression-free survival (PFS) in patients carrying SETD2 abnormalities ("SETD2 ab") but wild-type
505 for TP53 or ATM deletion and/or mutation compared to those with TP53 abnormalities ("TP53 ab")
506 and those wild-type for TP53, ATM and SETD2 ("Wild-type"). **2F.** Kaplan-Meier and log-rank analysis
507 for overall survival (OS) in the same categories described in E.
