Longitudinal methods for life course research: A comparison of sequence analysis, latent class growth models, and multistate event history models for studying partnership transitions

Julia Mikolai
Mark Lyons-Amos
ABSTRACT

This paper compares and contrasts three methods that are useful for life course researchers; the more widely used sequence analysis, the promising but less often applied latent class growth models, and multistate event history models. The strengths and weaknesses of each method are highlighted by applying them to the same empirical problem. Using data from the Norwegian Generations and Gender Survey, changes in the partnership status of women born between 1955 and 1964 are modelled, with education as the primary covariate of interest. We show that latent class growth models and multistate event history models are a useful addition to life course researchers’ methodological toolkit and that these methods can address certain research questions better than the more commonly applied sequence analysis or simple event history analysis.

KEYWORDS

Life course methodology; sequence analysis; latent class growth models; multistate event history models; Norway; partnership transitions; family life course.

EDITORIAL NOTE

Dr Julia Mikolai is a Research Associate in the School of Environmental Sciences at the University of Liverpool.

Dr Mark Lyons-Amos is a Research Fellow in Population Health at the London School of Economics and Political Science.

Corresponding author: Dr Julia Mikolai, J.Mikolai@liverpool.ac.uk.
ACKNOWLEDGEMENTS

While completing most of this work, Júlia Mikolai was a PhD student at the Department of Social Statistics and Demography at the University of Southampton and was funded by a +3 Scholarship provided by the Economic and Social Research Council (ES/J500161/1). Mark Lyons-Amos was a post-doctoral research fellow at the University of Southampton, funded by the European Research Council Starting Grant CHILDCOHAB (PI Dr Brienna Perelli-Harris). The authors would like to thank Dr Agnese Vitali for her comments and suggestions on a previous draft of this paper. The Harmonized Histories data file was created by the Non-Marital Childbearing Network (http://www.nonmarital.org). The GGS data were obtained from the GGP Data Archive and refer to the publication that contains the model survey instruments: United Nations 2005. Generations & Gender Programme: Survey Instruments. New York and Geneva: UN, 2005. The authors acknowledge the use of the IRIDIS High Performance Computing Facility, and associated support services at the University of Southampton, in the completion of this work.

1. INTRODUCTION
In the last half century, family life courses have changed considerably. For example, the transition to parenthood has been delayed, non-marital cohabitation and non-marital childbearing have become more common, as have union dissolution and re-partnering. Additionally, the timing and sequencing of family life events has changed resulting in more complex and less predictable family life courses. These changes have generated an increased interest in the applicability of different methods for modelling life courses with their complexities. Although a number of methods are available to study the family life course, discussion has mainly been limited to comparing simple event history models and sequence analysis (Billari, 2001b, 2005; Billari and Piccarreta, 2001, 2005; Piccarreta and Billari, 2007).

Simple event history analysis is commonly used to examine single or competing events (Heuveline and Timberlake, 2004; Perelli-Harris and Gerber, 2011; Perelli-Harris et al., 2010). Applications of event history analyses vary in focus and complexity. For example, recent studies (Baizán, Aassve, and Billari, 2003, 2004) applied simultaneous equations models to study the determinants of several concurrent life course transitions. Others used multilevel multiprocess models to account for correlated event histories (Steele, Kallis, Goldstein, and Joshi, 2005). These “event based” approaches primarily focus on the (causal) influence of certain covariates on particular events. Simultaneous models improve upon simple event history models by accommodating possible interdependencies between several events via modelling joint processes and unobserved heterogeneity. Even so, they limit attention to studying a specific segment of the life course.

Others have promoted the use of sequence analysis arguing that, unlike event history analysis, this “holistic approach” examines the life course trajectory as a whole meaningful unit. This technique creates “ideal-types” of trajectories that categorise and describe different life course patterns (Billari, 2001a, 2001b, 2005; Billari and Piccarreta, 2005; Piccarreta and Billari, 2007). It is then possible to assess how different covariates influence the probability of an individual to belong to one of these “ideal-types”.

Despite the availability of other techniques only a few studies have investigated their applicability to life course research. For example, Barban and Billari (2012) compared and
tested the consistency of sequence analysis and latent class analysis. Additionally, Bonetti, Piccarreta, and Salford (2013) proposed an extension of multistate models to studying the family life course. This paper aims to contribute to this line of research by comparing the strengths and weaknesses of sequence analysis and two other promising techniques: latent class growth models, and multistate event history models. These methods combine the properties of the event based and the holistic approaches by focusing on several consecutive events and thus are ideal to examine the family life course.

By applying these methods to a real life example, the differences and similarities as well as the strengths and weaknesses of these approaches are emphasised. Our application focuses on the role of education on changes in partnership status (i.e. being never partnered, transition to first cohabitation and first marriage, the dissolution of a first cohabitation or a first marriage, and forming a new partnership after union dissolution) of Norwegian women born between 1955 and 1964. We ask the following questions, pertinent to life course research: How can sequence analysis, latent class growth models and multistate event history models be used for studying the influence of education on partnership transitions over the early family life course? What types of research questions can be answered using these methods? And are these methods applicable to the same problems to the same extent or is one of them better than the other and if so in which situation?

2. DATA
We illustrate similarities and differences between sequence analysis, latent class growth models, and multistate event history models using data from the first wave of the Norwegian Generations and Gender Survey\(^1\) (GGS) from 2007/2008. We examine the influence of educational attainment on changes in partnership status of women born between 1955 and 1964 (\(N = 1290\)). The dataset includes extensive retrospective information on the start and end date (year and month) of up to five cohabitating and marital unions as well as union dissolutions. Cohabitation is defined as a co-residential relationship which lasted for at least three months. For this application Norwegian data are used because in Norway variation in partnership experiences is one of the largest compared to other European countries (Elzinga

---

\(^1\) This paper used the version that is available in the Harmonized Histories (Perelli-Harris, Kreyenfeld, and Kubisch, 2010).
and Liefbroer, 2007). This enables us to demonstrate the strengths and weaknesses of the examined methods using a rich dataset with more complex partnership experiences.

Although the Norwegian GGS provides cross-sectional weights, not all applied methods are able to incorporate these. Therefore, the analyses presented in this paper do not incorporate weights. This implies that the results might not be representative of the overall distribution of the examined partnership formation behaviours in Norway. However, this is not a major limitation because the aim is not to provide population estimates but to explore how the different methods can be applied to the same problem.

3. METHODS AND MODELLING STRATEGY

3.1. SEQUENCE ANALYSIS

Sequence analysis (SA) represents each individual life course by a sequence (i.e. a character string, which indicates the order and duration of states occupied by an individual in each year). For example, the sequence SSSCCMMMM means that the respondent was never partnered\(^2\) (S) for three months followed by two months of cohabitation (C) and four months of marriage (M). Due to the large possible number of combinations of states, usually very few individuals experience the exact same sequence. To reduce the number of sequences, Optimal Matching Analysis (OMA) is used.

OMA is a technique that measures the dissimilarity between sequences by identifying how similar pairs of sequences are. Similarity is defined in terms of the number, order, and duration of states within sequences. The algorithm calculates the similarity/dissimilarity between two sequences by taking into account three possible operations: replacement (one state is replaced by another one), insertion (an additional state is added to the sequence), and deletion (a state is deleted from the sequence). The fewer operations are needed to turn one sequence into the other, the more similar two sequences are and vice versa. Furthermore, to each operation, a certain cost can be attached. Therefore, identifying the relative cost of all operations is critical to determining (dis)similarity between sequences. These require \( a \ priori \)

\(^2\) Throughout this study never partnered women are defined as those who have never lived in a co-residential union for at least three months.
definition by the researcher with little objective measure of the correct specification, and results can be highly sensitive to these specifications (Brzinsky-Fay and Kohler, 2010). Then, the distance between two sequences is defined by the minimum costs of the operations that are necessary to transform one sequence into the other (Abbott and Tsay, 2000). The distances are recorded in a dissimilarity matrix.

Then, in order to find existing patterns in the data, k means cluster analysis is performed on this dissimilarity matrix. The aim of the cluster analysis is to minimise the within cluster and maximise the between cluster distance. The researcher needs to specify the number of clusters to be extracted from the data either a priori or by using fit statistics. Once the clusters are formed, they can be described with respect to the variables used to create the clusters (in this example partnership experiences). The clusters can be used both as independent and dependent variables in further analyses. Additionally, sequences can also be compared based on the number of episode changes within once sequence, the length of the sequences, or the number of different events in a sequence (Brzinsky-Fay and Kohler, 2010).

In our application, clusters are created based on women’s monthly partnership trajectories between age 15 and 40. After performing OMA with equal costs assigned to insertion and deletion (in this instance 1), individuals are allocated to clusters based on Ward’s distance. We assess the number of clusters based on two measures of average cluster linkage; the Calinski–Harabasz pseudo-F index (Calinski and Harabasz, 1974) and the Duda–Hart index (Duda and Hart, 1973). These statistics help to determine the optimal number of clusters by comparing the ratio of the within cluster distances to the between cluster distances. Additionally, the Duda-Hart index also produces a pseudo T-statistic\(^3\). Once the optimal number of clusters is established, cluster allocation is used as a response variable in a multinominal logistic regression. The models are estimated using the SQ-Ados ado for Stata 12 (Brzinsky-Fay, Kohler, and Luniak, 2006).

3.2. LATENT CLASS GROWTH MODELS

Latent Class Growth Models (LCGMs) are an extension of conventional growth curve models with the assumption that individuals are drawn from different subpopulations (latent

\[ \frac{1}{\frac{1}{\text{var}_{ct}}^{2}} = 1 + \frac{\tau^2}{N_1 + N_2 - 2}, \]

where \( N_c \) denotes the number of observations in cluster \( c \).
classes) that have different growth trajectories (Perelli-Harris and Lyons-Amos, 2015). Similarly to SA, these models have an individual centred perspective, thus they seek to identify relationships between individual response patterns and form groups based on these patterns (Jung and Wickrama, 2008). Individuals’ relationship histories are recorded at each age and then grouped into latent classes. The response (in this application partnership state in each year) is defined as the random variable $y_{i,age}$ with the following categories: never partnered (0), persistent cohabitation (1), marriage (2), and separated (3). After separation, individuals are allowed to re-enter cohabitation or marriage. Respondents move between these partnership states between age 15 and 40$^4$.

The specification of the growth curves and the robustness checks are similar to those in Perelli-Harris and Lyons-Amos (2015). Classes are formed based on yearly partnership histories$^5$. Individuals’ partnership histories form trajectories which are combined to form the latent classes. Latent classes describe different partnership patterns across individuals’ life courses. Each woman has a probability of belonging to each latent class. The closer an individuals’ partnership history is to the class trajectories, the more likely she is to belong to a particular latent class. The probability of being in partnership state $s$ at a given age is defined as $\pi_{i,age}^s = P(y_{i,age} = s)$ where $i$ stands for individuals. The probability of each partnership (compared to marriage which is the reference category) across the life course is modelled as a growth equation (see Equation 1). A separate growth equation is specified for each class $C_j$ ($j = 1 \ldots 5$) which are defined by a class-specific intercept ($\alpha_j^s$) and class-specific slope parameters ($\beta_{1,2,3,4,j}^s$).

$$\ln \left( \frac{\left(\pi_{i,age}^s | C_j = j \right)}{\sum_{s=2}^{4} \left(\pi_{i,age}^s | C_j = j \right)} \right) = \alpha_j^s + \beta_{1,j}^s age_i + \beta_{2,j}^s age_i^2 + \beta_{3,j}^s educ + \beta_{4,j}^s educ$$ (1)

In order to examine the relationship between the latent classes and education LCGMs offer two possibilities. First, education can be used to predict the probability of belonging to a certain latent class (Wang, Hendricks Brown, and Bandeen-Roche, 2005). This approach is

$^4$ If two partnership states are present in the same year, the higher value is selected. This means that short episodes of e.g. cohabitation or being separated before re-partnering will be missed.

$^5$ We use yearly (instead of monthly) intervals to reduce the size of the dataset and to increase the speed of estimation. Robustness checks for similar analyses have shown that the reduction of information from monthly to yearly intervals do not substantially influence the results (Perelli-Harris and Lyons-Amos, 2015).
comparable to SA. Where LCGMs have an advantage over SA is that they can also allow for education to alter the shape of the growth curves. The parameter $\beta_{3,j}$ expresses how the inclusion of educational level alters the intercept while $\beta_{4,j}$ indicates the influence of education on the slope of the growth curves. An additional advantage of LCGMs compared to SA is that a variety of fit statistics are available for deciding the optimal number of classes and this choice can be validated via simulation since the estimates are model based. However, the different criteria and test statistics (such as AIC, BIC or Lo-Mendell-Rubin Likelihood Ratio Test) can lead to different and sometimes contradictory conclusions (Nylund, Asparouhav, and Muthen, 2007).

In our application, we explore a set of 2, 3, 4, and 5 class models and perform the Lo-Mendell-Rubin-Likelihood Ratio Test (LMR-LRT) for all classes. This test examines the improvement in model fit for a J class model compared to a J-1 class model. In case of a 2 class model, it is equivalent to testing whether the LCGM performs better than a simple latent growth curve model, which assumes that one growth curve is enough to describe women’s partnership behaviours. The models are estimated in Mplus 6.2 for Linux, via the iridis-3 cluster computer provided by the University of Southampton. Note that we do not explore models with more than 5 classes. Due to the specification of partnership state as a nominal variable, the implementation of this model is not part of the main Mplus language. As a result, model estimation is computationally intense both due to the difficulty of the calculations required and the volume of data to be read.

### 3.3. MULTISTATE EVENT HISTORY MODELS

Multistate event history models differ from SA and LCGMs in that they do not aim to classify or group individuals. It is a variable-centred approach where the main purpose is to establish statistical relationships between the independent variable(s) and several transitions. Multistate event history models are an extension of simple event history models; rather than examining one transition, this approach allows individuals to move among different states over time. These movements are assumed to be stochastic and are modelled by means of

---

6 Exploratory analyses revealed that higher order classes tend to be sparsely populated with limited interpretability.

7 Although it can be argued that multi-state models predict group membership in terms of state occupation probabilities, in multi-state models individuals move from one state to the next. However, in SA and LCGMs each individual can only belong to one cluster or class.
transition probabilities. Thus, multistate event history models allow for examining covariate effects on several transitions within the same model.

Figure 1: Multistate event history model.

Note: S – never partnered, C – cohabitation, M – direct marriage, CM – marriage preceded by cohabitation with the same partner, D – union dissolution, R – re-partnering.

Another distinct advantage of this method is the possibility to include time-varying covariates and thereby examine how the influence of a variable of interest changes over the family life course. For example, it is possible to examine the influence of educational attainment, which may change over the life course, on several family life transitions. This cannot be done using simple event history models, SA or LCGMs. Multistate models assume the Markov property; that is that the present behaviour of an individual is enough to predict its future behaviour (Andersen and Keiding, 2002; Hougaard, 1999). For example, it would assume that the transition probability from marriage to union dissolution is the same for all married individuals irrespective of whether they have cohabited before marriage. As life course theory emphasises that earlier transitions play an important role in later transitions, this assumption is not realistic. In order to be able to examine the partnership transitions in a dynamic way, the model can be extended. We do so by defining the state ‘CM’ to differentiate between direct marriage and marriage that was preceded by cohabitation. One disadvantage of multistate event history models is that as the number of states increases and as individuals move along the life course, one might end up with small cell sizes and thus, with unreliable estimates of the transition hazards.

Figure 2 shows the multistate event history model, where the following states are defined: never partnered (S), cohabitation (C), direct marriage (M), marriage that was preceded by cohabitation with the same partner (CM), union dissolution (D) and re-partnering (R). We do not distinguish between cohabitation and marriage as a form of re-
partnering due to relatively small cell sizes and to keep the models comparable. The multistate event history model is estimated using a stratified continuous-time Cox model where each transition is represented by a different stratum (de Wreede, Fiocco, and Putter, 2011; Putter, Fiocco, and Geskus, 2007; Putter, van der Hage, de Bock, Elgalta, and van de Velde, 2006). Covariates are incorporated as transition-specific covariates to allow for their effect to differ across transitions. The transition hazard of individual $k$ is given by:

$$\lambda_{ij}(t|\mathbf{Z}) = \lambda_{ij,0}(t) \exp(\beta_{ij}^{\top} \mathbf{Z}_{ij})$$  \hspace{1cm} (2)$$

where $ij$ indicates a transition from state $i$ to state $j$, $\lambda_{ij,0}(t)$ is the baseline hazard, $\mathbf{Z}$ is the vector of covariates at baseline and $\mathbf{Z}_{ij}$ is the vector of transition-specific covariates.

In this application, we use monthly information on partnership experiences. To estimate the model, an augmented dataset is used with one row per transition for which the individual is at risk. Women are observed from age 15, when they are never partnered until age 40, the time of the survey or the time when they experience re-partnering, whichever happens earlier. As educational attainment is defined as a time-varying categorical variable, additional episode splitting is performed where an educational transition happens within an at-risk period. The models are estimated using the $mstate$ package in R (de Wreede et al., 2011).

4. VARIABLES

4.1. LEVEL OF EDUCATION

In all three models, the highest level of education at the time of the survey is measured by a variable with the following categories: low (ISCED 0 to ISCED 2), medium (ISCED 3 and ISCED 4), and high education (ISCED 5 and ISECD 6). High education is the reference category in all three models. In the multistate event history models, education is measured as a time-varying variable which is created using information on the year and month of reaching the highest level of education. We assume continuous education from age 15 and that secondary education takes 4 years while tertiary education takes 3 years on average. Missing information (7.9%) on the year and/or month of reaching the highest level of education was
imputed using information on the median age of finishing education by educational level. In LCGMs and SA, education is time-constant and indicates the highest level of education at the time of the survey.

5. RESULTS

5.1. SEQUENCE ANALYSIS

Table 1 presents the Calinski–Harabasz and the Duda–Hart indices for 2 to 6 cluster models. On the Calinski–Harabasz and Duda–Hart indices, higher values indicate more distinct clustering, whereas for the related Duda–Hart Pseudo T-square measure, lower values are indicative of more distinct grouping.

Table 1: Calinski–Harabasz and Duda–Hart indices for k cluster specifications.

Note: Numbers in boldface indicate the best fit for the given index.

There is disagreement between these indices as to the optimal number of clusters. The Calinski–Harabasz index indicates a 3 cluster solution while the Duda-Hart indices indicate a 4 cluster solution to be optimal. As two out of three measures indicate that a 4 cluster solution is preferable, we proceed with a 4 cluster model.

Figure 3 depicts the results of cluster analysis. The first cluster (Figure 3, panel a) is characterised by late partnership formation, where the first partnership is typically long term cohabitation or cohabitation which translates into marriage. Additionally, some women enter marriage directly. Therefore, this cluster is titled ‘late, varied partnerships’. Women who belong to the second cluster form first partnerships at a somewhat younger age than those in the first cluster (Figure 3, panel b). Most of these partnerships are direct marriages. Unions
which start as cohabiting partnerships later translate into marriage, and most of these partnerships are stable. This cluster is, thus, named the ‘(direct) marriage’ cluster. The third cluster (Figure 3, panel c) consists of women who experience early and long term cohabitation with relatively high union instability. Therefore, this group is referred to as the ‘cohabitation’ cluster. Finally, the fourth cluster (Figure 3, panel d) consists of women who experience early and direct marriage, hence the cluster is called ‘early, direct marriage’ cluster.

After having identified these four clusters, we apply multinomial logistic regression to assess how educational attainment influences the likelihood of women to belong to one of the four clusters (Table 2). To facilitate the interpretation of the regression coefficients, predicted probabilities are calculated (Table 3). The results show that more educated women have a higher probability to belong to the first cluster (late and varied partnerships) than lower educated women. Moreover, low educated women are more likely to belong to the (direct) marriage cluster (cluster 2) than medium or high educated women. Additionally, low and medium educated women are more likely to be in the cohabitation cluster (cluster 3) and in the early, direct marriage cluster (cluster 4) than those with high education.

### 5.2. LATENT CLASS GROWTH MODELS

Table 4 presents fit statistics for 2, 3, 4 and 5 class models. The LMR-LRT p-value indicates that the 2 class model is an improvement over a 1 class model, justifying the LCGM approach. All fit statistics indicate improving model fit with the addition of higher order classes. From the examined models, the 5 class model demonstrated the best model fit based on AIC, BIC and Sample Size BIC (SSBIC) statistics. Although the Lo-Mendell-Rubin Likelihood Ratio Test (LMR-LRT) indicates that a 4 class model is adequate, we select a 5 class model since this is the optimal number of classes according to all other fit statistics.

**Table 4**: Fit statistics for 2, 3, 4 and 5 class models

**Note**: Numbers in boldface indicate the best fit based on the given statistic.

Figure 4 (panel A to E) presents partnership profiles for the five extracted classes by educational attainment. Class 1 captures early and varied partnership forms, with an initial increase in the probability of both cohabitation and marriage for all educational levels. The probability of marriage peaks around the age of 24 for high and medium educated and at 22 for low educated, and declines thereafter. The probability of cohabitation rises, plateauing at age 22 for high and medium educated and at age 19 for low educated, before increasing again from around age 31 onwards. These relationships, formed at relatively early ages, are unstable; the probability of separation is high across all partnership forms and educational levels. There is some variation in how the probability of separation changes over age by educational attainment. For women with high or medium education, the probability of separation increases and remains high until age 40. In contrast, for low educated women it reaches its maximum at age 35 and falls thereafter, corresponding to an increase in the probability of post-separation cohabitation.

Class 2 broadly represents a long-term cohabitation pattern. Most women at all educational levels form cohabiting relationships from their early 20s, with a peak in the probability of cohabitation around the age of 28 for high and medium educated women and at age 25 for low educated women. Thereafter, the probability of being in a cohabiting relationship decreases among women with high and medium education coinciding with an increasing probability of marriage from around age 31 (which reaches 0.45 for highly educated women and 0.39 for women with medium education). In contrast, women with low education continue to exhibit a high probability of cohabitation (nearly 0.7 at age 40). Consequently, the corresponding increase in the probability of marriage is limited, reaching only 0.2 by age 40. This result indicates that low educated women are less likely to formalise
their unions. Additionally, the probability of separation is more than twice as high among low educated women as among their more educated counterparts.

Class 3 describes a generally early transition to marriage with some pre-marital cohabitation. Women with high and medium education have very similar partnership experiences: partnership formation begins with a small bump in the probability of cohabitation, followed by a transition to marriage with a 50% chance of being married around age 22. The probability of marriage is close to 1 among these women in their late 20s and it remains high with little evidence of separation. The patterns are slightly different for women with low education. Entry into partnership occurs earlier, with a decline in the probability of being single already from age 15. The probability of pre-marital cohabitation is higher among low educated women than among their more educated counterparts (peaking around 0.3 compared to under 0.2 for both medium and high educated women). In this class, marriage tends to occur at later ages.

Class 4 represents the most ‘modern’ partnership form with a considerably high incidence of cohabitation before marriage, with a peak at age 25, when the probability of cohabitation is roughly 0.4. Thereafter, many unions translate into marriage, the probability of which peaks around age 31. We observe roughly similar patterns of partnership formation for women of all educational levels but there are considerable differences in the timing of different partnership transitions. Women with low education tend to enter partnerships later than the more educated. Among low educated women, the probability of remaining never partnered stays close to 1 until age 21 while among medium and high educated women, this happens around age 18. Additionally, women with low education are less likely to experience cohabitation before marriage; the peak of the probability of being in a cohabiting relationship is roughly 0.35, compared to 0.40 and 0.47 for women with high and medium education, respectively.

Finally, Class 5 captures a more complex pattern of late partnership formation. Irrespective of educational level, the probability of being never partnered does not decline until after age 25 and it never falls below 0.2. After age 25, union forms are varied; the most and the least educated are more likely to form cohabiting unions than marriages at all ages while women with medium education are more likely to be married after age 37. Finally, there is some incidence of union instability in this class at later ages.

To further facilitate the interpretation of educational differences across classes, Table 5 presents the predicted probabilities of class membership by education. This table indicates that medium and highly educated women have a higher probability to belong to the ‘early marriage with some cohabitation’ class (Class 3) and to the ‘marriage preceded by cohabitation’ class (Class 4) than their low educated counterparts. Additionally, low educated women have a much higher probability (0.52) to belong to the ‘early, varied partnerships class’ (Class 1) compared to those with medium education or higher (0.15 and 0.11, respectively). Last, we did not find large educational differences in the predicted probability of belonging to Class 2 (‘early cohabitation with late transition to marriage’) and Class 5 (‘late and heterogeneous partnerships’). These results indicate that women with higher educational attainment generally experience more complex partnership patterns. The modal class for women with low education is Class 1 (‘early, varied partnerships’) while for medium and highly educated women it is Class 3 (‘early marriage with some cohabitation’) although their probability to belong to Class 4 (‘marriage preceded by cohabitation’) is also larger than that of the other classes.

5.3. MULTISTATE EVENT HISTORY MODEL

Table 6 describes the number of women who were at risk of each transition (total entering) and the number and proportion of those who experienced them. In the examined sample, 70% of never partnered women formed a cohabiting union while 28% got married. Over two thirds of cohabiting unions transitioned to marriage while 22% ended in union dissolution. A similar proportion (25-26%) of marriages (both direct marriage and marriage that was preceded by cohabitation) ended with union
dissolution. Finally, 75% of women who experienced union dissolution formed a new partnership.

Table 6: Number (and proportion, %) of women who experience each partnership transition

The results of the multistate event history model are summarised in Table 7. Higher educated never partnered women have a higher risk of entering cohabitation and direct marriage than medium and low educated. Furthermore, education has a positive gradient on the transition from cohabitation to marriage; low and medium educated cohabiting women are 45% and 32% less likely, respectively, than their highly educated counterparts to marry their cohabiting partner. Following union dissolution, women with low education are less likely to find a new partner compared to highly educated women. Education does not have a significant influence on the dissolution of a cohabiting or a marital union (whether or not it was preceded by cohabitation).

6. CONCLUSION AND DISCUSSION

This paper compared three methodological approaches (i.e. sequence analysis, latent class growth models, and multistate event history models) to the analysis of life course data focusing on the influence of education on partnership experiences of Norwegian women born between 1955 and 1964. These methods have several similarities and differences. For example, sequence analysis and latent class growth models establish the relationship between education and the probability of belonging to certain groups (clusters or classes) based on women’s partnership experiences. In our application, sequence analysis revealed four clusters based on women’s partnership experiences (late, varied partnerships; (direct) marriage; cohabitation; and early, direct marriage), latent class growth models suggested five partnership classes (early, varied partnerships; early cohabitation with late translation to marriage; early marriage with some cohabitation; marriage preceded by cohabitation; and late, heterogeneous partnerships). Multistate event history models do not classify individuals but rather examine the influence of education on every partnership transition thereby enabling us to draw conclusions about the changing influence of education over the early family life course.

Overall, the examined methods arrive at similar conclusions with respect to the influence of education on partnership experiences. For example, sequence analysis suggests that higher educated women are more likely to belong to the late, varied partnerships cluster. Similar conclusions can be drawn from the results of multistate models; more educated women were found to have a higher risk of finding a new partner following union dissolution than their lower educated counterparts. However, the results of the LCGMs did not suggest significant educational differences in the
probability of belonging to the ‘late and heterogeneous partnerships’ class (Class 5). Additionally, sequence analysis revealed that the more educated are less likely to belong to the cohabitation cluster than their lower educated counterparts. Multistate event history models showed that never partnered highly educated women have higher risks to enter cohabitation than their lower educated counterparts. At the same time, these women are also more likely to marry their cohabiting partner and thus less likely to remain cohabiting. This is in line with the results of sequence analysis. However, LCGMs did not find educational differences in the probability of belonging to Class 2 (‘early cohabitation with late transition to marriage’). Moreover, while sequence analysis showed that low educated women have a higher probability to belong to the ‘(direct) marriage’ cluster and the ‘early, direct marriage’ cluster, multistate models revealed the opposite; the more educated have a higher risk of experiencing direct marriage than the lower educated. Additionally, the results of LCGMs showed that low educated women are the most likely to belong to the ‘early, varied partnerships’ class (Class 1). Finally, both LCGMs and multistate event history models found that women with higher education are more likely to marry their cohabiting partner, while no conclusions can be drawn based on the results of SA with respect to this transition.

The examined methods have different properties and approach studying the life course in a different way. In order to emphasise the strengths of each technique and to accommodate their limitations, the presented analyses could not have been implemented in exactly the same way for the three techniques. For example, the multi-state event history model and sequence analysis was estimated using monthly data while the LCGMs relied on yearly data due to computational issues. This implies that in LCGMs the number of transitions might be underestimated and some variation in life courses might be lost. Additionally, the multi-state event history model incorporated a time-varying education variable while the other two methods investigated the association between the highest level of education at the time of the interview (i.e. a time constant variable) and partnership formation. Finally, while the multi-state event history model estimated the influence of education on first, and second and higher order partnership transitions separately (in order to emphasise this feature of the model) LCGMs and SA did not distinguish between first and higher order unions.
These differences in the implementation of the analyses could potentially explain some of the differences in the results of the multi-state event history model and the other two methods but they cannot account for differences between the results of SA and LCGMs. However, it has been shown that SA and LCGMs should not be expected to give the same answer. Using simulated data, Warren, Halpern-Manners, Luo, and Raymo (2012) showed that the number of trajectories these methods produce might differ from each other as well as from the true number of trajectories. Moreover, LCGMs and SA might assign the same individuals to different trajectory groups. Replicating the result of SA with five clusters (results not shown) revealed that the cohabitation cluster was further split into two, more homogeneous (but also much smaller) clusters: a cohabitation cluster and a separation cluster (although a very small one with around 80 individuals). This indicates that beyond our selected cluster specification, clusters are becoming too small to be reliable.

Even though the applications are not exactly the same and occasionally they provide somewhat different results, by illustrating the properties and application of the different techniques, we were able to identify similarities and differences between these methods with respect to their ability to address certain desirable aspects of studying the family life course. These are summarised in Table 8.
Based on our findings, we can formulate broad recommendations for researchers choosing between different life course methods. First, sequence analysis is best applied to research questions which attempt to describe partnership behaviours of different groups of women and the overall associations of these groups with certain covariates. This can be achieved through the method’s ability to classify individuals and allow for covariates to predict women’s membership in the different clusters. Overall, fitting the model does not require a lot of computing power and because the procedure is not model based, the user is protected against baseline misspecification (i.e. no baseline needs to be specified). Although not presented in this paper, the method can also calculate transition intensities between the different states. As it is not possible to condition sequences, or more importantly transition probabilities, on covariate information or to allow for the incorporation of changing covariate information over the life course, this method cannot answer research questions relating to the changing influence of a variable over the life course.
Second, latent class growth models have a number of similar properties to sequence analysis. Its main advantage is that it is able to incorporate more complicated structures by, for example, allowing for covariate information to alter the shape of partnership trajectories. Unfortunately, the implementation of LCGMs is computationally intense and requires considerable computing power to estimate models for large datasets. Moreover, as LCGMs are model based, a greater degree of robustness is required particularly when estimating the shape of the growth curves. On the other hand, this also means that a greater variety of fit-statistics is available than in sequence analysis, where the decision of the optimal number of clusters is more arbitrary than in LCGMs. Last, it should be noted that while LCGMs allow for testing the model performance via simulation approaches (e.g. Nylund et al., 2007), such a test is not available for sequence analysis. Thus, LCGMs are most suited to studying complex research topics where the aim is to identify differences in covariate effects between groups of individuals. The present paper has demonstrated this by extracting different classes of partnership behaviour and comparing the effect of educational attainment within these classes.

Finally, although multistate event history models do not classify individuals in the same way as the previous two techniques, there are a number of distinct advantages to using this method. For example, the estimation of transition intensities allows for examining several transitions over the life course within the same model as well as for estimating the changing influence of covariates over the life course by allowing for the incorporation of time-varying covariates. Neither sequence analysis, nor latent class growth models are capable of studying changing covariate effects over the life course. Additionally, the use of a stratified Cox model provides some protection against baseline misspecification. To conclude, multistate event history models can best answer research questions specifically related to changing covariate effects over the life course. For example, as this paper has shown, it can estimate the changing influence of education on different partnership transitions over the early family life course.

The analyses presented in this study have some limitations. First, the multistate event history model assumes that the hazards of the examined transitions for women with different educational level are proportional. This assumption might not
be realistic. The multi-state event history model would allow for the incorporation of interaction effects between age and education in order to relax the assumption of proportional hazards. However, LCGMs and SA are unable to explicitly incorporate such interactions. To keep the models comparable, we refrained from including interactions between age and education in the multi-state event history model. Second, next to education many factors may influence the timing and sequencing of partnership transitions. For LCGMs and SA, which included a time-constant education variable, the influence of other time-constant covariates on the timing and sequencing of the examined transitions could have been studied. However, in the examined dataset time-varying information, which was used in the multi-state event history model, could only be reconstructed for education. Including more covariates for LCGMs and SA but not for the multi-state event history model would not have facilitated the comparison of the methods and the results they produce. Researchers can build on this simple application and perform more complex analyses.

Taken together, by comparing sequence analysis, latent class growth models, and multistate event history models, this paper contributed to the discussion on the applicability of different methods for studying the life course. We showed that latent class growth models and multistate event history models are a useful addition to life course researchers’ methodological toolkit and that these methods can address certain research questions better than the more commonly applied sequence analysis or simple event history analysis. In particular, we have stressed the types of research questions that may be better addressed using these techniques which provide new insights in the field of life course studies.

8 It would be possible to build sequences of changes in educational level and examine these sequences together with sequences of partnership states.

Improving our understanding of the key drivers and implications of population change
