**Summary**

- Ca\(^{2+}\)-dependent signalling processes enable plants to perceive and respond to diverse environmental stressors, such as osmotic stress. A clear understanding of the role of spatiotemporal Ca\(^{2+}\) signalling in green algal lineages is necessary in order to understand how the Ca\(^{2+}\) signalling machinery has evolved in land plants.
- We used single-cell imaging of Ca\(^{2+}\)-responsive fluorescent dyes in the unicellular green alga *Chlamydomonas reinhardtii* to examine the specificity of spatial and temporal dynamics of Ca\(^{2+}\) elevations in the cytosol and flagella in response to salinity and osmotic stress.
- We found that salt stress induced a single Ca\(^{2+}\) elevation that was modulated by the strength of the stimulus and originated in the apex of the cell, spreading as a fast Ca\(^{2+}\) wave. By contrast, hypo-osmotic stress induced a series of repetitive Ca\(^{2+}\) elevations in the cytosol that were spatially uniform. Hypo-osmotic stimuli also induced Ca\(^{2+}\) elevations in the flagella that occurred independently from those in the cytosol.
- Our results indicate that the requirement for Ca\(^{2+}\) signalling in response to osmotic stress is conserved between land plants and green algae, but the distinct spatial and temporal dynamics of osmotic Ca\(^{2+}\) elevations in *C. reinhardtii* suggest important mechanistic differences between the two lineages.

**Introduction**

The ability of an organism to sense and respond to its environment is fundamental for its survival. In plants, calcium (Ca\(^{2+}\))-dependent signalling processes play a central role in the response to many environmental stimuli, including mechanical stimulation, osmotic stress, oxidative stress and temperature shock (Knight et al., 1992, 1997; Takahashi et al., 1997; Kiegle et al., 2000; Pei et al., 2000). It is likely that the development of these signalling pathways helped plants to colonize land and become the dominant primary producers in terrestrial ecosystems. However, our ability to understand how and why these important signalling processes have evolved in plants is limited, as the role of Ca\(^{2+}\) signalling in response to environmental stimuli in the green algae (Chlorophyta), which represent the other major lineage in the Viridiplantae, is not well characterized.

Many of the diverse environmental stimuli encountered by plants give rise to activation of Ca\(^{2+}\)-permeable channels in the plasma membrane or internal membranes, leading to transient elevations in cytosolic Ca\(^{2+}\) ([Ca\(^{2+}\)]\(_{\text{cyt}}\)) which are sensed by a range of downstream effector proteins (such as calmodulin (CaM), calmodulin-like proteins (CMLs), the calcium-dependent protein kinases (CDPKs) or the calcineurin B-like (CBL) calcium sensor proteins and their CBL-interacting protein kinases (CIPKs)) (Hetherington & Brownlee, 2004; Edel & Kudla, 2015). As [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations are generated by a wide variety of stimuli, the spatial and temporal dynamics of each [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevation are important in conveying specificity (McAinsh & Pittman, 2009; Whalley et al., 2011). For example, plant [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations can take the form of brief spikes, extended elevations or a series of oscillations. In combination with the broad range of downstream responders, the distinct spatiotemporal dynamics of [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations enable the cell to use Ca\(^{2+}\) signalling in response to many different stimuli.

Vascular plants lack clear homologues of several important classes of Ca\(^{2+}\) channel found in animal cells, such as the four-domain voltage-dependent Ca\(^{2+}\) channels (VDCCs), the transient receptor potential (TRP) channels and the inositol triphosphate receptor (IP\(_{3}\)R) (Wheeler & Brownlee, 2008; Verret et al., 2010; Edel & Kudla, 2015). However, these channels are present in green algal genomes (Merchant et al., 2007; Wheeler & Brownlee, 2008), suggesting that there may be important differences in the signalling mechanisms between plants and green algae. While [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in plants have been extensively characterized (McAinsh & Pittman, 2009), direct observations of [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in green algae remain limited. [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations have been observed in response to ‘light-off’ stimuli in the...
freshwater alga *Eremosphaera viridis* (Bauer et al., 1997) and during the settlement of *Ulva linza* zoospores (Thompson et al., 2007). [Ca\(^{2+}\)]\(_{cyt}\) elevations relating to the deflagellation process have been extensively characterized in the freshwater alga *Chlamydomonas reinhardtii* (Wheeler et al., 2008). *Chlamydomonas reinhardtii* can excise its flagella via a Ca\(^{2+}\)-dependent signalling pathway in response to various stressors, including osmotic stress (Quarmby, 1996; Meijer et al., 2002). The addition of 20 mM external Ca\(^{2+}\) to *C. reinhardtii* led to a series of repetitive [Ca\(^{2+}\)]\(_{cyt}\) elevations that were linked to the process of flagellar excision (Wheeler et al., 2008). The rapid and dynamic nature of these [Ca\(^{2+}\)]\(_{cyt}\) elevations in *C. reinhardtii* was considerably different from those observed in vascular plants, where [Ca\(^{2+}\)]\(_{cyt}\) transients commonly last for many seconds. Repetitive [Ca\(^{2+}\)]\(_{cyt}\) spiking in vascular plants also generally occurs over timescales of minutes rather than seconds (e.g. Ca\(^{2+}\) spiking in root hairs induced by nodulation factors) (Wais et al., 2000).

*Chlamydomonas reinhardtii* is a motile organism, which may account for the dynamic nature of some of the signalling processes within the cell. The motile responses of swimming *C. reinhardtii* cells to light have been well documented and are mediated by changes in flagellar Ca\(^{2+}\) ([Ca\(^{2+}\)]\(_{fla}\)). Voltage-gated Ca\(^{2+}\) channels in the flagella are activated by a whole-cell depolarization mediated by channelrhodopsin, a light-gated ion channel situated in the plasma membrane adjacent to the eyespot (Harz & Hegemann, 1991; Fujiu et al., 2009). In addition to swimming, *C. reinhardtii* cells can move by adhering to a substrate via their flagella and gliding along that surface (Bloodgood, 1981). Gliding motility is mediated by the movement of adherent glycoproteins in the flagellar membrane, which are driven along the length of the flagellar axosome by the microtubule motors responsible for intraflagellar transport (IFT) (Collingridge et al., 2013; Shih et al., 2013). We have previously demonstrated that the movement of IFT proteins during gliding motility is regulated by flagellar Ca\(^{2+}\) signalling (Collingridge et al., 2013). The flagella of gliding *C. reinhardtii* cells are arranged at 180° to each other and gliding motility initiates when the pulling force in one flagellum overcomes the resistance of the other (Bloodgood, 1981). Direct observation of flagellar Ca\(^{2+}\) ([Ca\(^{2+}\)]\(_{fla}\)) in gliding *C. reinhardtii* cells indicates the potential for complex and highly dynamic signalling, with each individual flagellum capable of generating very rapid, repetitive [Ca\(^{2+}\)]\(_{fla}\) elevations independently of the cytosol and the other flagellum (Collingridge et al., 2013).

While the role of Ca\(^{2+}\) signalling in flagellar-related processes in *C. reinhardtii* is well established, its role in regulating processes in the cell body has been less thoroughly explored. Recent progress indicates a role for Ca\(^{2+}\) in the cellular responses to nutrient starvation (Motiwalla et al., 2014) and in regulating photoacclimation, through the activity of the chloroplast-localized calcium sensor protein (CAS) (Petroutsos et al., 2011). However, the dynamics of [Ca\(^{2+}\)]\(_{cyt}\) elevations in response to these and other environmental stimuli in *C. reinhardtii* have not been characterized.

In order to gain a better understanding of the role of Ca\(^{2+}\) signalling in green algae, we performed a detailed examination of the dynamics of [Ca\(^{2+}\)]\(_{cyt}\) elevations generated by *C. reinhardtii* cells in response to osmotic stress. We found that salinity stress and hypo-osmotic stimuli induced [Ca\(^{2+}\)]\(_{cyt}\) elevations with distinct spatial and temporal characteristics. Hypo-osmotic stress also induced repetitive [Ca\(^{2+}\)]\(_{fla}\) elevations that were independent of [Ca\(^{2+}\)]\(_{cyt}\), indicating that the flagella, although continuous with the cytosol, can act as distinct Ca\(^{2+}\) signalling compartments in response to environmental stimuli.

### Materials and Methods

#### Algal strains and growth conditions

*Chlamydomonas reinhardtii* Dangeard strains CC1021 mt\(^+\) (wild type) and cw15 (CCAP 11/32 CW15+, cell wall deficient) were obtained from the Chlamydomonas Resource Center (University of Minnesota, St Paul, MN, USA) and the Culture Collection of Algae and Protozoa (Scottish Association for Marine Science, Oban, UK), respectively. The ift20 IFT20-mCherry strain was a gift from Karl Lechtreck (Lechtreck et al., 2009). Cultures were grown in standard Tris-acetate-phosphate (TAP) liquid medium at 23°C with a 16 h : 8 h, light : dark cycle and a light intensity of 100 μmol m\(^{-2}\) s\(^{-1}\).

#### Biolistic loading of dextran-conjugated fluorescent dyes

Cells were simultaneously loaded with two fluorescent dyes, the Ca\(^{2+}\)-responsive dye Oregon Green-BAPTA Dextran (OG) (10 000 MW) and the reference dye Texas Red Dextran (TR) (10 000 MW) (Invitrogen Ltd, Paisley, UK). Dextran-conjugated dyes were used to avoid the problems with dye compartmentalization commonly found with plant and algal cells (Bothwell et al., 2006). OG was used for this study rather than Fluo-4 dextran used previously (Wheeler et al., 2008) as OG has a much greater fluorescence than Fluo-4 when in the Ca\(^{2+}\) unbound state, which reduces technical issues associated with chlorophyll autofluorescence and also aids imaging of the flagella by Total Internal Reflection Fluorescence (TIRF) microscopy. *Chlamydomonas reinhardtii* cells were concentrated by centrifugation (400 g for 5 min) and washed with biolistic loading buffer (BLB) (10 mM HEPES, pH 7.4, 20 μM K\(^+\) glutamate and 50 mM sorbitol), and then biolistic loading was performed using a Bio-Rad PDS-1000 delivery system with 1100-psi rupture discs, as described previously (Wheeler et al., 2008). Samples were washed and resuspended in TAP medium and left for 2 h to recover under normal growth conditions. After this period, loaded cells were chosen that were able to swim and glide normally, indicating that they were fully recovered from the loading process. We confirmed that the biolistically loaded fluorescent dyes were correctly localized to the cytosol of *C. reinhardtii*, using confocal laser microscopy (Zeiss LSM510; excitation 488 nm; emission 500–530 and 650–710 nm). The dyes demonstrated a homogenous cytosolic localization, with no evidence of compartmentalization. Chlorophyll autofluorescence was negligible relative to OG, allowing us to subsequently use epifluorescent microscopy to image [Ca\(^{2+}\)]\(_{cyt}\).
Ca\textsuperscript{2+} imaging

Before imaging, cells were resuspended in Chlamydomonas Assay Buffer (CAB) containing 5 mM HEPES, 1 mM HCl, 1 mM KCl, 0.2 mM Ethylene glycol-bis(2-aminoethyl ether)-N,N,N',N'‘-tetraacetic acid and 0.5 mM CaCl\textsubscript{2} with pH adjusted to 7.4 using N-methyl-d-glucamine (NMDG). Free Ca\textsuperscript{2+} was calculated to be 301 μM using MaxChelator (http://maxchelator.stanford.edu/). Cells were placed in 35-mm glass-bottomed dishes (In Vitro Scientific, Sunnyvale, CA, USA) coated with 0.01% poly-L-lysine (Sigma-Aldrich, St Louis, MO, USA) to encourage adherence of the cells. Cells were perfused with CAB buffer at a flow rate of 3 ml min\textsuperscript{-1} during imaging.

Cells were imaged by epifluorescence microscopy at room temperature using a Nikon Eclipse Ti with a ×100, 1.49 NA oil immersion objective and detection with a Photometrics Evolve EM-CCD camera (Photometrics, Tucson, AZ, USA). Simultaneous excitation of OG and TR was performed using 488- and 561-nm lasers (Coherent, Santa Clara, CA, USA). A Dual-View beam splitter device (Photometrics, Tucson, AZ, USA) was used to detect emission at 500–550 and 575–625 nm, respectively. Images were captured using NIS-ELEMENTS v.3.1 software (Nikon, Japan) with a 200–300-ms exposure (frame rate of 3.33–5 frames s\textsuperscript{-1}). The same microscopy equipment was used in TIRF mode for flagellar imaging. IFT20-mCherry was visualized in TIRF mode using 561-nm laser excitation and 575–625-nm emission.

NaCl shocks were delivered by rapidly switching the perfusion from CAB to CAB + 50–400 mM NaCl. Hypo-osmotic treatments were delivered by switching the perfusion to deionized water containing 50 μM CaCl\textsubscript{2}. To investigate the response to hypo-osmotic shock in the absence of contractile vacuole activity, cells were equilibrated to CAB containing 100 mM sucrose for at least 1 h. In order to assess whether extracellular Ca\textsuperscript{2+} is involved in [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in response to osmotic shock, cells were initially perfused with Ca\textsuperscript{2+}-free CAB (containing 200 μM EGTA without added CaCl\textsubscript{2}) and a hypo-osmotic shock was administered using deionized water containing 50 μM EGTA (adjusted to pH 7). In order to assess the involvement of mechanosensitive ion channels in the generation of [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations, cells were pretreated for at least 10 min with a final concentration of either 5 μM GsMTx4 (Smartox Biotechnology, Saint-Martin-d’Hères, France) or 10 μM Ruthenium red (RuR) (Sigma-Aldrich) before the perfusion with distilled water or distilled water containing 10 μM RuR, respectively. RuR did not exhibit any fluorescent properties that interfered with Ca\textsuperscript{2+} imaging.

Data processing

Changes in [Ca\textsuperscript{2+}]\textsubscript{cyt} were identified by calculating the fluorescence intensity ratio between OG and TR for a defined region of interest within each C. reinhardtii cell. Ratio traces were smoothed using a Savitsky–Golay filter (window 5, order 2) and a baseline trace was created using an asymmetric least squares smoothing baseline algorithm (ORIGINPRO 2016; OriginLab Corporation, Northampton, MA, USA) (Supporting Information Fig. S1). The smoothed OG/TR traces were divided by the baseline trace to determine the relative change in fluorescence. [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations were defined as any increase in OG/TR fluorescence above a threshold value (3%) that persisted for more than one frame. We calculated that an OG/TR ≥ 3% required a minimum signal to noise ratio (SNR) of 10, with SNR defined as signal intensity/SD of noise. Contractile vacuole activity was detected by measuring changes in the fluorescence intensity of TR in a region of interest encompassing each contractile vacuole. For visualization of [Ca\textsuperscript{2+}]\textsubscript{cyt} dynamics in cells, IMAGEJ software was used to divide each OG image by a rolling median image from 20 frames to produce a pseudocoloured ratio image. Previous researchers have demonstrated that standard Ca\textsuperscript{2+} ionophores do not work well in C. reinhardtii (Braun & Hegemann, 1999), which precludes an in vivo calibration of OG. We therefore performed an in vitro calibration of this dye using Calcium Calibration Buffer Kit no. 1 (Life Technologies Ltd, Paisley, UK), allowing the increase in [Ca\textsuperscript{2+}]\textsubscript{cyt} for a given change in fluorescence to be estimated, assuming a resting [Ca\textsuperscript{2+}]\textsubscript{cyt} of 100 nM (Fig. S2). Data obtained from all treatments are shown as mean ± SE.

Results

Salt stress induces a single [Ca\textsuperscript{2+}]\textsubscript{cyt} elevation in Chlamydomonas reinhardtii

In order to examine whether Ca\textsuperscript{2+} signalling processes are conserved between vascular plants and green algae, we applied four external stimuli that routinely induce [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in plants to C. reinhardtii strain CC1201. We found that hydrogen peroxide (up to 20 mM) and mannitol (up to 400 mM) did not induce [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in C. reinhardtii (Fig. 1a,b). However, NaCl and hypo-osmotic shock resulted in [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations and these stimuli were therefore examined in greater detail. We examined Ca\textsuperscript{2+} signalling in response to salt stress in two C. reinhardtii strains, the CC1021 wild-type strain and cw15, a cell wall deficient mutant. Application of 300 mM NaCl to CC1021 resulted in [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in nine out of 61 cells. These cells exhibited a single rapid [Ca\textsuperscript{2+}]\textsubscript{cyt} elevation lasting for 2.04 ± 0.33 s that occurred 7.04 ± 0.73 s after the stimulus was applied. The mean maximal amplitude of the OG/TR increase was 8.93 ± 0.97%, which equates to a mean maximal [Ca\textsuperscript{2+}]\textsubscript{cyt} of 184 nM, assuming a resting [Ca\textsuperscript{2+}]\textsubscript{cyt} of 100 nM. The nature of the [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations was highly consistent, although it is clear that only a small proportion of the cells exhibit this response (14.8%), suggesting that a threshold stimulus is required to trigger a [Ca\textsuperscript{2+}]\textsubscript{cyt} elevation. Very few [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations were observed at lower concentrations of NaCl (no cells responded at 150 mM (n = 11) and only one out of 12 cells at 200 mM NaCl). Higher concentrations of NaCl (400 mM) shrank the cells excessively, preventing accurate determination of [Ca\textsuperscript{2+}]\textsubscript{cyt}. Previous researchers have demonstrated that Ca\textsuperscript{2+}-dependent signalling pathways in C. reinhardtii can be influenced by the concentration of external Ca\textsuperscript{2+} in the surrounding media (Quarmby & Hartzell,
However, we found that CC1021 cells acclimated to 10 mM external Ca\(^{2+}\) showed a high frequency of spontaneous [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations, making it difficult to examine their response to NaCl (Fig. S3).

Ca\(^{2+}\) signalling in the cell wall-deficient strain cw15 was significantly more sensitive to salinity stress than in CC1021. We found that 50 mM NaCl induced a single [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevation in 55% of cw15 cells (n = 14), with a mean maximal increase in the OG : TR ratio of 8.0 ± 0.9% (176 nM [Ca\(^{2+}\)]\(_{\text{cyt}}\)) which occurred 14.4 ± 1.5 s after the application of the stimulus (Fig. 2). Treatment of cw15 cells with higher concentrations of NaCl (70, 90 and 120 mM) resulted in progressive increases in the mean maximal amplitude of the [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations and in the proportion of cells exhibiting [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations (Fig. 2). The delay between the stimulus and the response also decreased. For example, 120 mM NaCl resulted in single [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in over 80% of cells. These [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations had a mean maximal amplitude of 16.8 ± 1.6% (equating to a [Ca\(^{2+}\)]\(_{\text{cyt}}\) of 261 nM) and occurred 4.7 ± 0.4 s after the application of the stimulus. We conclude that the timing and amplitude of NaCl-induced [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations are sensitive to the intensity of the stimulus, which may contribute to specificity in downstream responses.

NaCl-induced [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations propagate as a fast Ca\(^{2+}\) wave

We next examined the spatial characteristics of [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations induced by NaCl. We found that the [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations induced by 300 mM NaCl in CC1021 originated in the apex of the cell and rapidly spread to the remainder of the cell, representing a fast Ca\(^{2+}\) wave (n = 5 cells examined where the apex of the cell could be clearly distinguished) (Fig. 3). [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations induced by 120 mM NaCl in cw15 also originated in the apical region and rapidly spread to the rest of the cell (n = 5 cells, Video...
Chlamydomonas reinhardtii is a small cell (5–10 μm), making it difficult to accurately determine the speed of the propagating Ca\(^{2+}\) wave. However, it was clear that the initial apical [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevation spread to the remainder of the cell within 0.5–1 s, representing a speed of c. 10–20 μm s\(^{-1}\). We have previously observed that 20 mM external Ca\(^{2+}\) can stimulate a Ca\(^{2+}\) wave that propagates from the apex of C. reinhardtii cells at a mean speed of 30 μm s\(^{-1}\) (Wheeler et al., 2008). These propagation speeds are similar to the fast Ca\(^{2+}\) waves in animal cells that are generated via the process of Ca\(^{2+}\)-induced Ca\(^{2+}\) release (CICR) from the endoplasmic reticulum (Jaffe, 2010). Our results also suggest that the apex of the C. reinhardtii cell plays an important role in sensing and responding to salt stress.

To examine whether the NaCl-induced [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in C. reinhardtii were dependent on Ca\(^{2+}\) influx from the external medium, we applied 120 mM NaCl to cw15 cells in the absence of external Ca\(^{2+}\) (i.e. CAB assay buffer containing 200 μM EGTA, but without added CaCl\(_2\)). We did not observe [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in any cells (n = 16). This indicates that an influx of external Ca\(^{2+}\) is required to initiate the [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations induced by NaCl, although the [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations may subsequently propagate through the release of Ca\(^{2+}\) from internal stores. The absolute dependence on external Ca\(^{2+}\) in C. reinhardtii contrasts with Arabidopsis, where NaCl-induced [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations were only partially repressed in the presence of La\(^{3+}\) or EGTA (Knight et al., 1997). NaCl-induced [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in Arabidopsis are also partially inhibited by nicotinamide, an inhibitor of Ca\(^{2+}\) release from internal stores by cyclic-ADP ribose (Abdul-Awal et al., 2016).

Hypo-osmotic stress induces a series of repetitive [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations

Hypo-osmotic stress causes a rapid influx of water into algal cells and may lead to catastrophic cell bursting if the cell cannot rapidly osmoregulate (Taylor et al., 1996). Chlamydomonas
**Spatial and temporal characterization of a \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation induced by hypo-osmotic shock in Chlamydomonas reinhardtii.** Spatial and temporal characterization of a \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation induced by hypo-osmotic shock in CC1201 was performed. The graph displays the change in fluorescence ratio (Oregon Green BAPTA dextran : Texas Red dextran (OG : TR)). The pseudocoloured images represent the change in fluorescence (ΔF/ΔF_0) in the OG and TR channels. The images show that the \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation in response to NaCl initiates in the apical region (arrowed) and rapidly propagates to the rest of the cell (200 ms per frame). The inset shows an expanded timescale of the \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation in apical, central and posterior regions of interest within the cell. The cell shown is representative of five CC1021 cells examined and similar spatial characteristics were observed in cw15 cells (n = 5). Bar, 5 μm.

**Hypo-osmotic stress induces repetitive \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations in Chlamydomonas reinhardtii.** Spatial and temporal characterization of a \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation induced by hypo-osmotic shock in CC1201 was performed. The graph displays the change in fluorescence ratio (Oregon Green BAPTA dextran : Texas Red dextran (OG : TR)). The pseudocoloured images represent the change in fluorescence (ΔF/ΔF_0) in the OG and TR channels. Hypo-osmotic shock was induced by rapid perfusion of deionized water containing 50 μM CaCl₂, leading to a series of rapid \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations that appear to be spatially uniform within the cell (300 ms per frame). The cell shown is representative of 31 cells examined. Bar, 5 μm.

reinhardtii exists in freshwater and soil environments, which are often hypotonic relative to the cytosol, and uses a contractile vacuole (CV) to expel excess water (Komsic-Buchmann et al., 2014). Preliminary hypo-osmotic shock experiments using diluted media (50%) failed to induce any \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations in C. reinhardtii strain CC1021. However, perfusion of C. reinhardtii cells with deionized water (containing 50 μM CaCl₂) routinely induced a series of repetitive \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations (Fig. 4). We observed at least one \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation in 71% of the cells (n = 31). The mean number of \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations observed within 60 s of hypo-osmotic shock was 3.93 ± 0.47 and the average duration of each \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation was 1.91 ± 0.50 s (n = 14 cells used for analysis). The mean maximal amplitude of the \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations was 6.08 ± 0.50%, equating to 166 nM \([\text{Ca}^{2+}]_{\text{cyt}}\) (n = 14 cells). The initial \([\text{Ca}^{2+}]_{\text{cyt}}\) elevation occurred 15.93 ± 1.53 s after the stimulus was applied. In contrast to \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations induced by NaCl, the \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations induced by hypo-osmotic shock did not originate in the apex and appeared to be uniformly distributed throughout the cytosol (Fig. 4). We did not observe \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations in the cell wall-deficient mutant cw15 in response to hypo-osmotic shock (n = 11 cells). To investigate this further, we examined the response to hypo-osmotic shock in two further C. reinhardtii strains. We did not observe any \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations in another cell wall-deficient strain CC3395 (n = 11 cells), but found that 53.9% of CC125 cells (a walled wild-type strain) exhibited \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations (n = 13).

The hypo-osmotic stress applied (deionized water containing 50 μM CaCl₂) provided a robust and reproducible stimulus that enabled us to study the nature of \([\text{Ca}^{2+}]_{\text{cyt}}\) signalling in C. reinhardtii. However, the ionic compositions of the pretreatment (CAB) and treatment solutions are not identical and it is possible that changes in pH, \([\text{Ca}^{2+}]_{\text{cyt}}\) or other ions also contributed to the observed \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations in addition to the change in osmolarity. To examine this possibility, we applied additional hypo-osmotic stimuli to C. reinhardtii cells. We did not observe \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations when cells acclimated to CAB + 50 mM sorbitol were returned to CAB (n = 7 cells). However, cells acclimated to CAB + 100 mM sucrose gave robust and reproducible \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations when switched to 10% CAB (adjusted to 300 μM CaCl₂ and pH 7.4) (seven out of 11 cells examined). This suggests that the \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations observed were not attributable to changes in \([\text{Ca}^{2+}]_{\text{cyt}}\) or pH. While we cannot rule out a contribution from other ions (e.g. Cl⁻), we conclude that the rapid switch to a solution of very low osmolarity is likely to be the primary contributor to the observed \([\text{Ca}^{2+}]_{\text{cyt}}\) elevations. The
initial hypo-osmotic stimulus (deionized water + 50 μM CaCl₂) was used for all further experiments.

The response to hypo-osmotic shock in CC1021 cells was dependent on the presence of external Ca²⁺. No cells exhibited [Ca²⁺]cyt elevations within 60 s of the hypo-osmotic stimulus in the absence of external Ca²⁺ (n = 21) (Fig. 5a). Our results suggest that an influx of external Ca²⁺ is required to trigger [Ca²⁺]cyt elevations in *C. reinhardtii* in response to hypo-osmotic stress. In many organisms, the activation of mechanosensitive ion channels during cell swelling plays a role in the generation of [Ca²⁺]cyt elevations in response to hypo-osmotic stress (Taylor et al., 1996; Nakayama et al., 2012). To test whether mechanosensitive ion channels are required for the initiation of [Ca²⁺]cyt elevations in *C. reinhardtii*, we applied RuR, a nonspecific inhibitor of mechanosensitive channels, and GsMTx4, a specific inhibitor of stretch-activated ion channels (Bowman et al., 2007) (Fig. 5a–e). Ten-micromolar RuR strongly inhibited [Ca²⁺]cyt elevations (only one out of 11 cells exhibited a single [Ca²⁺]cyt elevation). Five-micromolar GsMTx4 resulted in a lower proportion of cells exhibiting [Ca²⁺]cyt elevations (38% compared with 71% in the untreated control; n = 16) and these cells only exhibited single rather than repetitive [Ca²⁺]cyt elevations. GsMTx4 did not have any effect on the timing and the duration of the initial [Ca²⁺]cyt elevation.

Ca²⁺-dependent signalling pathways have been implicated in the regulation of CV activity in several unicellular protists (Allen & Naitoh, 2002; Ladenburger et al., 2006). However, we observed no direct correlation between the timing of [Ca²⁺]cyt elevations in *C. reinhardtii* and the water expulsion (systole) events of the CV. Furthermore, we found no evidence to suggest that Ca²⁺ signalling influenced the frequency of systole events during hypo-osmotic shock. The mean time between systole events was 21.8 ± 1.0 s in control cells and was 17.8 ± 0.7 s during hypo-osmotic shock (n = 13 cells). In Ca²⁺-free media, the mean time between systole events was 21.4 ± 1.2 s in untreated control.
control cells and 18.4 ± 0.4 s during hypo-osmotic shock (n = 18 cells). In cells treated with 10 μM RuR, the mean time between systole events was 20.6 ± 1.2 s before and 20.5 ± 1.1 s during hypo-osmotic shock (n = 17 cells). The timing of systole events between the treatments was not statistically significant (one-way ANOVA; Holm–Sidak post hoc test). To examine whether the \( [Ca^{2+}]_{\text{cyt}} \) elevations could be generated in the absence of CV activity, we acclimated \( C. \text{reinhardtii} \) cells to mildly hypertonic medium (CAB + 100 mM sucrose) to minimize CV activity (Komsic-Buchmann et al., 2012). Application of a hypo-osmotic shock to these cells resulted in significant swelling of the cell body and led to restoration of CV activity within 1–2 min. Multiple \( [Ca^{2+}]_{\text{cyt}} \) elevations were only observed in 50% of these cells (nine out of 18) and these were primarily restricted to the period before the onset of full CV activity (Fig. S4). The remaining cells did not exhibit \( [Ca^{2+}]_{\text{cyt}} \) elevations, but still showed full restoration of CV activity. Thus, the \( [Ca^{2+}]_{\text{cyt}} \) elevations induced by hypo-osmotic shock are not dependent on CV activity and are not required for the initiation of CV activity.

\( [Ca^{2+}]_{\text{cyt}} \) elevations induced by hypo-osmotic shock do not induce deflagellation

\( Chlamydomonas \) \( \text{reinhardtii} \) cells have two flagella c. 10 μm in length that are used for swimming and gliding motility. Although the two flagella represent only 0.27% of the total cell volume (assuming a cell radius of c. 5 μm), they constitute a much larger proportion of the cell surface area (c. 7.2%) and may therefore play an important role in osmotic signalling responses. Certain osmotic stimuli have previously been shown to induce deflagellation. For example, application of 50 mM KCl to \( Chlamydomonas \) \( \text{moewusii} \) caused rapid deflagellation (within 30 s), whereas higher concentrations of KCl caused a much slower deflagellation response (Meijer et al., 2002). As deflagellation is directly induced by \( [Ca^{2+}]_{\text{cyt}} \) elevations (Wheeler et al., 2008), we examined whether the \( [Ca^{2+}]_{\text{cyt}} \) elevations observed in \( C. \text{reinhardtii} \) during either NaCl or hypo-osmotic stress triggered the deflagellation response. Using differential interference contrast (DIC) microscopy, we found that salinity stress induced by 300 mM NaCl for 30 s did not result in deflagellation in CC1021 cells (zero out of 43 cells deflagellated). Applying a hypo-osmotic stress for 30 s also did not induce deflagellation (0 out of 50 cells deflagellated). Examination of cells loaded with \( Ca^{2+} \)-responsive dyes confirmed that deflagellation does not occur during \( [Ca^{2+}]_{\text{cyt}} \) elevations induced by hypo-osmotic shock (seven cells examined where flagella could be visualized). Therefore, the observed \( [Ca^{2+}]_{\text{cyt}} \) elevations induced by these stressors are not linked to the deflagellation process.

Hypo-osmotic shock induces compartmentalized \( Ca^{2+} \) elevations in flagella

We next examined whether hypo-osmotic shock was able to induce \( Ca^{2+} \) elevations in flagella and whether these were related to the observed \( [Ca^{2+}]_{\text{cyt}} \) elevations. We have previously demonstrated that large \( [Ca^{2+}]_{\text{cyt}} \) elevations (induced by the addition of external \( Ca^{2+} \)) can result in simultaneous \( [Ca^{2+}]_{\text{fla}} \) elevations in both flagella (Wheeler et al., 2008). However, it is also clear that \( [Ca^{2+}]_{\text{fla}} \) elevations in individual \( C. \text{reinhardtii} \) flagella can occur independently of the cytosol and the other flagellum (Collingridge et al., 2013). Using TIRF microscopy to specifically visualize flagella, we found that hypo-osmotic shock resulted in multiple rapid \( [Ca^{2+}]_{\text{fla}} \) elevations in 76.7% of flagella examined (n = 26), with an average of 3.06 ± 0.27 \( Ca^{2+} \) elevations per flagellum (Fig. 6a,b). Addition of 10 μM RuR completely inhibited the \( [Ca^{2+}]_{\text{fla}} \) elevations caused by hypo-osmotic shock.

We found that the rapid \( [Ca^{2+}]_{\text{fla}} \) elevations induced by hypo-osmotic shock in one flagellum did not routinely coincide with \( [Ca^{2+}]_{\text{fla}} \) elevations in the other flagellum, suggesting that each flagellum acts as an independent \( Ca^{2+} \) signalling compartment (Fig. 6c). To examine whether \( [Ca^{2+}]_{\text{fla}} \) elevations coincided with \( [Ca^{2+}]_{\text{cyt}} \) elevations, we used a pseudo-TIRF imaging approach, altering the angle of the excitation light so that we could simultaneously image the flagella and the apical region of the cell body of \( C. \text{reinhardtii} \). We found that the repetitive \( [Ca^{2+}]_{\text{cyt}} \) and \( [Ca^{2+}]_{\text{fla}} \) elevations induced by hypo-osmotic shock do not coincide and exhibit no apparent relationship (Fig. 6d) (n = 8 cells). Furthermore, \( [Ca^{2+}]_{\text{fla}} \) elevations were observed in cells that did not demonstrate \( [Ca^{2+}]_{\text{cyt}} \) elevations. The results suggest that the flagella and the cytosol can act as independent \( Ca^{2+} \) signalling compartments in response to hypo-osmotic shock.

\( [Ca^{2+}]_{\text{fla}} \) elevations modulate flagella-mediated gliding motility of \( C. \text{reinhardtii} \) cells by regulating the accumulation of IFT particles and their associated molecular motors (Collingridge et al., 2013; Shih et al., 2013). We found that hypo-osmotic shock caused gliding CC1021 cells to withdraw their flagella from the 180° configuration, suggesting that the pulling force in each flagellum had been disrupted (Fig. 7a,b). When cells were returned to the original medium, the flagella began to pull forward once more and they rapidly returned to their typical 180° orientation. The effect of hypo-osmotic shock on gliding motility was inhibited by 10 μM RuR (Fig. 7b). We next examined the impact of hypo-osmotic shock on the accumulation of IFT particles using a \( C. \text{reinhardtii} \) strain expressing the IFT20-mCherry reporter fusion (Lechtreck et al., 2009). We found that the typical accumulation of IFT particles found in stationary flagella was disrupted following hypo-osmotic shock, with retrograde transport returning the IFT particles to the cell body (Fig. 7c). In each case, disruption of accumulated IFT particles coincided with the withdrawal of the flagellar tip (n = 27 flagella). When the cells were restored to the assay buffer, the flagellar tips moved forward and IFT particles began to accumulate again. Together, these observations suggest that the \( [Ca^{2+}]_{\text{fla}} \) elevations observed during hypo-osmotic shock influence flagellar-mediated gliding motility through their action on the accumulation of IFT particles (Collingridge et al., 2013).

Discussion

\( Chlamydomonas \) \( \text{reinhardtii} \) \( [Ca^{2+}]_{\text{cyt}} \) elevations in response to NaCl stress

Rapid signalling responses to osmotic stimuli are required by nearly all eukaryote cells to prevent swelling or shrinking of the
cell which may be potentially damaging. Ca\(^{2+}\)-dependent signalling pathways play a critical role in these responses in land plants, and evolution of specific Ca\(^{2+}\) signalling properties probably played a major role in the successful colonization of terrestrial environments. Our results demonstrate that Ca\(^{2+}\) signalling is likely to be involved in the response of green algae to osmotic stimuli, although the nature of these signals and the manner in which they are generated are likely to differ significantly from those in land plants.

We found that *C. reinhardtii* cells responded to NaCl stress with a single rapid Ca\(^{2+}\) elevation. The timing and the amplitude of the signal were dependent on the strength of the stimulus, with larger Ca\(^{2+}\) elevations observed at the higher NaCl concentrations. Many aspects of these Ca\(^{2+}\) elevations are similar to those observed in vascular plants. Studies using the Ca\(^{2+}\)-responsive bioluminescent reporter aequorin revealed that Arabidopsis roots exhibit a single [Ca\(^{2+}\)]\(_{\text{cyt}}\) transient when exposed to salt stress (Knight *et al.*, 1997). The amplitude of the [Ca\(^{2+}\)]\(_{\text{cyt}}\) elevations in Arabidopsis roots was also observed to be greater with increasing NaCl concentration (Tracy *et al.*, 2008). However, care must be taken when comparing results obtained using aequorin to single cell imaging, as aequorin reports the mean [Ca\(^{2+}\)]\(_{\text{cyt}}\) concentration within a population of cells and therefore will not reflect complex spatial and temporal changes in [Ca\(^{2+}\)]\(_{\text{cyt}}\) in an individual cell (Dodd *et al.*, 2006). Single-cell imaging of the moss *Physcomitrella patens* indicated that protonema cells exhibited a single sustained [Ca\(^{2+}\)]\(_{\text{cyt}}\) transient in response to 250 mM NaCl (Qudeimat *et al.*, 2008), whereas Arabidopsis roots exhibited a

**Fig. 6** Hypo-osmotic shock induces repetitive [Ca\(^{2+}\)]\(_{\text{fla}}\) elevations in the flagella. (a) Total Internal Reflection Fluorescence (TIRF) microscopy image of a *Chlamydomonas reinhardtii* cell loaded with Oregon Green BAPTA dextran, demonstrating the specific visualization of gliding flagella with minimal interference from the cell body. (b) Frequency histograms indicating the [Ca\(^{2+}\)] elevations in the cytosol (*n* = 16) and flagella (*n* = 15) following hypo-osmotic shock. Bin size = 10 s. (c) Simultaneous measurement of [Ca\(^{2+}\)]\(_{\text{fla}}\) elevations in two flagella from a single cell in response to hypoosmotic shock. Both flagella exhibit repetitive [Ca\(^{2+}\)]\(_{\text{fla}}\) elevations, although these do not coincide with each other. The trace is representative of 15 cells examined. (d) Simultaneous measurement of [Ca\(^{2+}\)] elevations in the flagellum and cytosol of a single cell in response to hypo-osmotic shock. The hypo-osmotic shock induces [Ca\(^{2+}\)]\(_{\text{fla}}\) elevations in both compartments, although these do not coincide and appear to be distinct from each other. Note that the amplitude of [Ca\(^{2+}\)]\(_{\text{fla}}\) elevations was much greater than those observed in the cytosol following hypo-osmotic shock. Bars, 5 μm.
biphasic $[\text{Ca}^{2+}]_{\text{cyt}}$ elevation in response to 100 mM NaCl, in which an initial rapid $[\text{Ca}^{2+}]_{\text{cyt}}$ elevation was followed by a much lower secondary $[\text{Ca}^{2+}]_{\text{cyt}}$ elevation (Bonza et al., 2013).

Our findings reveal some important distinctions between the NaCl-induced $[\text{Ca}^{2+}]_{\text{cyt}}$ elevations in single plant cells and those observed in *C. reinhardtii*. The $[\text{Ca}^{2+}]_{\text{cyt}}$ elevations in *C. reinhardtii* are very rapid, rising and returning to basal levels within 5 s, and propagate from the apex of the cell as a fast Ca$^{2+}$ wave. Fast Ca$^{2+}$ waves in animal cells involve the sequential Ca$^{2+}$-dependent activation of inositol triphosphate receptors (IP3Rs) in the endoplasmic reticulum, leading to a spatially propagating $[\text{Ca}^{2+}]_{\text{cyt}}$ elevation. Fast Ca$^{2+}$ waves have not been characterized in detail in individual cells of land plants, with the exception of a UV-induced fast Ca$^{2+}$ wave in *Physcomitrella patens* caulonema cells (Tucker et al., 2005), although spontaneous Ca$^{2+}$ elevations in Arabidopsis guard cells can exhibit spatial propagation (Yang et al., 2008). Recently, Choi et al. (2014) demonstrated that the application of NaCl to root tips induces an ultrafast intercellular Ca$^{2+}$ wave in Arabidopsis that spreads very rapidly along whole-plant tissues at 400 μm s$^{-1}$. The mechanism through which this ultrafast Ca$^{2+}$ wave propagates between plant cells is not yet clear, although the speed of the wave was drastically reduced in mutant plants defective in the vacuolar localized two-pore channel TPC1 (Choi et al., 2014). Plant genomes lack homologues of the IP3R, which may contribute to the apparent absence of typical fast Ca$^{2+}$ waves in most plant cells (Krinke et al., 2007). By contrast, IP3R homologues are present in several algae, including *C. reinhardtii* (Wheeler & Brownlee, 2008; Verret et al., 2010), where they could potentially contribute to the propagation of a Ca$^{2+}$ wave during salt stress.

Given the requirement for external Ca$^{2+}$, the NaCl-induced $[\text{Ca}^{2+}]_{\text{cyt}}$ elevations in *C. reinhardtii* are likely to require

**Fig. 7** Hypo-osmotic shock influences flagellar-mediated gliding motility. (a) Differential interference contrast microscopy images of gliding *Chlamydomonas reinhardtii* CC1021 cells. The images show the position of the flagella in a representative cell immediately before hypo-osmotic shock (left), after application of hypo-osmotic shock for 30 s (middle) and after return to normal assay buffer for 30 s (right). (b) Mean straightness of the flagella during hypo-osmotic shock treatment in control cells ($n = 20$) and cells treated with 10 μM Ruthenium red (RuR; $n = 24$). Straightness was defined as the distance measured from tip A to tip B, divided by the total length of the flagellum. (c) Kymograph displaying the movement of intraflagellar transport (IFT) protein IFT20-mCherry along the flagellum, visualized by Total Internal Reflection Fluorescence (TIRF) microscopy. The anterograde (towards the tip) and retrograde (towards the cell body) movements of IFT particles can be visualized as diagonal lines on the kymograph. Pseudocolour is used to indicate the changes in the fluorescence of IFT20-mCherry as it accumulates. In the example shown, the IFT particles have accumulated in the stationary flagellum, but these are rapidly dispersed via retrograde IFT following hypo-osmotic shock. The IFT particles do not accumulate during the duration of the hypo-osmotic shock, but following the return to normal assay conditions, the IFT particles begin to accumulate and the flagellum begins to glide forward. Bars, 5 μm. Error bars denote SE.
activation of Ca\textsuperscript{2+}-permeable channels in the plasma membrane, presumably at the cell apex. In Arabidopsis, it has been suggested that Annexin1 (ANN1), a putative plasma membrane Ca\textsuperscript{2+}-permeable channel, is responsible for a Ca\textsuperscript{2+}-dependent Ca\textsuperscript{2+} influx in the presence of 220 mM NaCl (Laohavisit et al., 2013). However, annexins have not yet been identified in the genome of *C. reinhardtii* (Jami et al., 2012). More recently, another Ca\textsuperscript{2+}-permeable channel, OSCA1, has been identified in plants that contributes to [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations induced by sorbitol (Yuan et al., 2014). Several homologues of OSCA1 have been identified in *C. reinhardtii* (Yuan et al., 2014; Edel & Kudla, 2015), although these form a distinct clade from the plant OSCA channels and so it remains to be seen whether they can also act as Ca\textsuperscript{2+} channels.

Repetitive Ca\textsuperscript{2+} elevations in response to hypo-osmotic shock

*Chlamydomonas reinhardtii* uses a very different osmoregulatory strategy from land plants to cope with hypotonic environments, using CVs to expel excess water instead of using a rigid cell wall to generate turgor (Komsic-Buchmann et al., 2014). It is likely that these different osmoregulatory strategies have a major impact on the signalling pathways associated with hypo-osmotic stress. Many different eukaryotes exhibit [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in response to hypo-osmotic stress, including plants, animals, fungi, trypanosomes, brown algae and diatoms (Taylor et al., 1996; Falcia- tore et al., 2000; Tatur et al., 2007; Hoffmann et al., 2009; Nakayama et al., 2012). In these organisms, two types of response are commonly observed; either a single [Ca\textsuperscript{2+}]\textsubscript{cyt} elevation or a biphasic response involving Ca\textsuperscript{2+} influx, followed by Ca\textsuperscript{2+} release from intracellular stores. By contrast, the [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations induced by hypo-osmotic stress in *C. reinhardtii* were highly repetitive in nature. Although repetitive [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in response to hypo-osmotic stress have been observed in animal cells, we are not aware of repetitive [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in photosynthetic organisms, suggesting that this may be a novel feature of the *C. reinhardtii* response.

In many organisms, the generation of [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in response to hypo-osmotic shock is linked to cell swelling and the activation of mechanosensitive ion channels (Taylor et al., 1996; Hoffmann et al., 2009; Nakayama et al., 2012). Previous researchers have demonstrated that mechanical stimulation of the cell body of *C. reinhardtii* results in inward Ca\textsuperscript{2+} currents that are sensitive to Gd\textsuperscript{3+}, a nonspecific blocker of mechanosensitive ion channels (Yoshimura, 1998). It seems likely that cell swelling in *C. reinhardtii* caused by hypo-osmotic shock activates mechanosensitive ion channels in the plasma membrane, leading to an influx of Ca\textsuperscript{2+}. Interactions between the cell wall and the plasma membrane may contribute to the response to hypo-osmotic stress, as we did not observe [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations in cell wall-deficient mutants, although it has been suggested that the absence of a cell wall in *C. reinhardtii* may alter the osmolarity of the cytosol, which could also influence the response to a hypo-osmotic stimulus (Hoffmann & Beck, 2005). In animal cells, the [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations induced by hypo-osmotic shock activate Ca\textsuperscript{2+}-activated K\textsuperscript{+} channels and induce solute release, preventing cell bursting and contributing to the regulatory volume decrease (Hoffmann et al., 2009). Ca\textsuperscript{2+} plays a similar role in osmotic adjustment in brown algae, with disruption of Ca\textsuperscript{2+} signalling leading to cell bursting in *Fucus* embryos (Taylor et al., 1996). As the [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations generated during hypo-osmotic shock in *C. reinhardtii* do not appear to contribute to the regulation of CV function, it is likely that they play a role in rapid osmotic adjustment.

Recent progress has begun to identify the molecular mechanisms involved in hypo-osmotic signalling in other eukaryotes. In fission yeast, two endoplasmic reticulum-localized mechanosensitive ion channels belonging to the MscS-like (MSL) family (Msy1 and Msy2) contribute to Ca\textsuperscript{2+} elevations generated during hypo-osmotic shock (Nakayama et al., 2012). Although plants contain a large family of MSL channels, their role in generating [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations is not clear and another group of mechanosensitive ion channels, the Mid1-complementing activity (MCA) proteins, probably contribute to Ca\textsuperscript{2+} influx during hypo-osmotic shock (Nakagawa et al., 2007; Haswell et al., 2008). *Chlamydomonas reinhardtii* does not possess MCA proteins and, although it possesses three MSL proteins, these may have other roles in the cell, as characterization of MSC1 revealed it to be a chloroplast-localized Cl\textsuperscript{−} channel (Nakagawa et al., 2007). *Chlamydomonas reinhardtii* does, however, contain an expanded family of TRP channels (Wheeler & Brownlee, 2008; Fujiu et al., 2011; Arias-Darraz et al., 2015) and this class of channel plays an important role in osmotic signalling in mammals (Hoffmann et al., 2009).

The role of the cell wall in osmotic Ca\textsuperscript{2+} signalling

We observed distinct Ca\textsuperscript{2+} signalling responses of walled and wall-less strains to osmotic stimuli. The wild-type walled strain CC1021 was much less sensitive to NaCl than the wall-less strain cw15, but conversely the wall-less strains did not exhibit Ca\textsuperscript{2+} elevations in response to hypo-osmotic stress. These observations suggest that the cell wall may contribute to osmotic signalling, although the underlying mechanisms are not yet clear. Interactions between the plasma membrane and the cell wall have been suggested to contribute to mechanical stimuli during both hypotonic and hyperosmotic stress in *Fucus* rhizoids (Taylor et al., 1996). Interactions with the cell wall could contribute to the [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations generated by hypo-osmotic stimuli in *C. reinhardtii*, as [Ca\textsuperscript{2+}]\textsubscript{cyt} elevations were not observed in wall-less strains, although they did respond to NaCl. The differing sensitivities of wall-less mutants to osmotic stimuli may also arise from the physiological consequences of the absence of a cell wall. Walled and wall-less strains exhibit similar levels of CV activity, suggesting that the cell wall only has a minor impact on water influx (Luykx et al., 1997; Komsic-Buchmann et al., 2012). Cytosolic osmolarity was estimated to be slightly greater in wall-less strains (Luykx et al., 1997; Komsic-Buchmann et al., 2012), which could influence the response to osmotic stimuli, although this does not appear to be the case in the response to hypo-osmotic stress, as we would expect the wall-less strains to be more sensitive rather than less sensitive.
Flagella act as independent Ca$^{2+}$ signalling compartments

Previous studies have found that *C. reinhardti*i flagella are mechanosensitive. Mechanical stimulation of *C. reinhardti*i flagella using a suction pipette results in a series of repetitive inward Ca$^{2+}$ currents (Yoshimura, 1996) and swimming cells exhibit a mechano-shock response (a brief period of backwards swimming), which is mediated by a flagellar-localized TRP channel (TRP11) (Fujiu et al., 2011). Similarly, applying a stretching force to a flagellum attached to a substrate results in repetitive flagella Ca$^{2+}$ elevations (Collingridge et al., 2013). It seems likely that water influx into the flagellum during hypo-osmotic shock may cause swelling, which could activate these mechanosensitive Ca$^{2+}$ responses. The dynamic [Ca$^{2+}$]$_{fla}$ elevations observed during hypo-osmotic shock may therefore contribute to localized osmotic adjustment in flagella, for example through the activation of Ca$^{2+}$-activated K$^+$ channels. Although we found that hypo-osmotic shock influenced gliding motility, it remains unclear whether this is simply a consequence of raising [Ca$^{2+}$]$_{fla}$ in this organelle. [Ca$^{2+}$]$_{fla}$ elevations contribute to the detachment of the flagella from the substrate by causing the dissociation of IFT particles from the adherent flagella membrane glycoproteins (Collingridge et al., 2013). During hypo-osmotic shock, this response may enable the previously immotile cell to detach from the substrate and move to more favourable areas. A potent inhibitor of Ca$^{2+}$-activated K$^+$ channels (ciliabrevin) was found to cause flagellar shortening and deflagellation in *C. reinhardti*i (Engel et al., 2011) and it will be interesting to determine whether this phenotype arises from an inability of flagella to osmoregulate.

The vastly different morphologies of the flagella and the cell body suggest that they will have differing sensitivities to osmotic stress. The ability of the cell to regulate Ca$^{2+}$ independently between the flagella and the cytosol enables a localized cellular response dependent on the nature of the stimulus. Although our results indicate localized Ca$^{2+}$ signalling in flagella during osmotic shock in *C. reinhardti*i, other flagellar signalling processes are strictly dependent on the cell body and include the well-characterized photoresponses in which light sensing by the eyespot leads to the activation of flagellar-localized Ca$^{2+}$ channels (Harz & Hegemann, 1991). *Chlamydomonas reinhardti*i flagella therefore represent highly dynamic excitable signalling compartments that can act either independently of or in combination with the cell body. Recent findings suggest that the motile cilia in mammalian cells are much less independent of the cell body, as ciliary Ca$^{2+}$ was found to be highly dependent on [Ca$^{2+}$]$_{cyt}$ (Doerner et al., 2015). Moreover, the nonmotile primary cilia of mammalian cells differ further as they have an elevated resting [Ca$^{2+}$] (750 nM) and do not exhibit dynamic changes in [Ca$^{2+}$] (Delling et al., 2013). These observations suggest that there is considerable diversity between organisms in the mechanisms underlying ciliary Ca$^{2+}$ elevations and their interactions with the cytosol.

There is considerable interest in the role of cilia as cellular sensors and their contribution to the generation of [Ca$^{2+}$]$_{cyt}$ elevations. The potential role of ciliary Ca$^{2+}$ signalling in mechanosensation by the nonmotile mammalian primary cilia has been extensively explored (Nauli et al., 2003). However, recent findings demonstrate that mechanical stimulation of primary cilia in kidney epithelial cells and the developing embryo and of the kinocilia of the ear do not induce ciliary Ca$^{2+}$ elevations (Delling et al., 2016). By contrast, there is considerable evidence supporting a role for ciliary Ca$^{2+}$ signalling in unicellular protists following mechanical stimulation (Eckert & Brehm, 1979; Yoshimura, 1996; Collingridge et al., 2013). Although *C. reinhardti*i flagella do appear to be directly mechanosensitive, in *Paramaecium caudatum* mechanosensation is initiated by the cell body rather than the cilium itself (Ogura & Machemer, 1980). Therefore, in many cases the hypothesis that cilia act as cellular sensors and contribute to the generation of [Ca$^{2+}$]$_{cyt}$ elevations must be viewed with caution.

We found no evidence to suggest that the [Ca$^{2+}$]$_{fla}$ elevations in *C. reinhardti*i contribute to [Ca$^{2+}$]$_{cyt}$ elevations. The [Ca$^{2+}$]$_{fla}$ elevations induced by hypo-osmotic shock are restricted to the flagella, although the possibility remains that these signalling processes could relay information to the cell body through other mechanisms, for example through the generation of mobile second messengers, which could allow detection of potentially damaging osmotic conditions before they influence the cell body directly. An osmosensor role has also been proposed for primary cilia of cholangiocytes in the mammalian biliary duct (Gradilone et al., 2007), although clearly the underlying mechanisms may differ. Further detailed examination of the interactions between [Ca$^{2+}$]$_{cyt}$ and [Ca$^{2+}$]$_{fla}$ elevations will be required to test whether *Chlamydomonas* flagella can also function as osmosensors for the cell body.

Conservation of Ca$^{2+}$ signalling in the green lineage

Our results demonstrate a role for Ca$^{2+}$ signalling the perception of environmental stimuli in the green algae. The central role for Ca$^{2+}$ in osmotic stress signalling appears to be conserved between the major lineages in the Viridiplantae, and this role is also conserved in many other eukaryotes. However, the nature of the [Ca$^{2+}$]$_{cyt}$ elevations in *C. reinhardti*i is distinct from those observed in vascular plants, exemplified by the fast Ca$^{2+}$ wave induced by salt stress or the multiple rapid [Ca$^{2+}$]$_{cyt}$ elevations in response to hypo-osmotic stress. These differences are probably attributable to a combination of the different Ca$^{2+}$ signalling toolkits found in plants and green algae and wider differences in their morphologies and physiological. Understanding these differences will not only provide much needed information on stress signalling in green algae but also help us understand the evolution of the signalling processes that enabled the colonization of terrestrial environments by land plants.
