Evaluating the Impact of User Behavior on D2D Communications in Millimeter-wave Small Cells

Chuhan Gao, Yong Li, Member, IEEE, Yong Niu, Depeng Jin, Member, IEEE, and Sheng Chen, Fellow, IEEE

Abstract—Small cells in millimeter-wave (mmWave) band are able to provide multi-gigabit access data rates, and have emerged as a cost-efficient solution to offer interference-free device-to-device (D2D) communications. In order to improve system performance and enhance user experience, direct transmissions between devices should be scheduled properly. We first propose a transmission scheduling scheme for radio access of small cells in mmWave band, termed directional D2D medium access control (D3MAC), whereby a path selection criterion is designed to enable D2D transmissions. Through extensive simulations, we demonstrate that D3MAC achieves near-optimal performance, and it outperforms other schemes significantly in terms of delay and throughput. Based on this near-optimal scheme, we then evaluate the impact of user behavior, including traffic mode and traffic load as well as user density, denseness and mobility, on the performance of D2D communications in mmWave small cells. Our study reveals that the performance of D2D communications is improved as the user density and denseness increase, but this effect is only obvious under heavy traffic loads. Furthermore, user mobility is shown to be another important factor that influences the performance of D2D communications in a complicated way. System performance is first improved as the average user speed increases from static, but performance is degraded significantly when the user speed becomes high.

I. INTRODUCTION

Mobile data traffic is increasing rapidly, and a 1000-fold increase by 2020 is predicted [1]. In order to increase mobile network capacity so as to meet the ever-increasing demand, device-to-device (D2D) communication is proposed to enable devices to communicate directly, which offers an underlaying to the cellular network for improving spectral efficiency [2], [3]. Under the control of base stations (BSs), user equipments (UEs) can transmit data to each other through direct links using cellular resources instead of through BSs. Consequently, it enables physical-proximity communication, which saves power while improving spectral efficiency dramatically. D2D communication is expected to be a key feature supported by next generation cellular networks [3].

On the other hand, there has been an increasing interest in deploying small cells underlying the conventional homogeneous macrocell network in the design of the next-generation mobile communication [4]. This network deployment is usually referred to as heterogeneous cellular networks. Small cell in millimeter-wave (mmWave) is a promising technology for future cellular networks to provide high data rate communications. Unlike existing communication systems which use lower carrier frequencies (e.g., from 900 MHz to 5 GHz), mmWave band small cells suffer from high propagation loss. The free space propagation loss at 60 GHz band is 28 decibels (dB) more than that occurred at 2.4 GHz [5]. Due to the directionality and high propagation loss, however, the interference between mmWave links is minimal. This is highly advantageous to D2D communications which involve discovering and communicating with nearby devices. Therefore, the potential of D2D communications in mmWave small cells to enhance the network performance is great. Proper scheduling over radio access for D2D transmissions in mmWave small cells is vital to fully realize this potential.

Moreover, it is necessary to investigate the fundamental factors that influence the achievable performance. Suffering from high propagation loss, mmWave D2D communications can only achieve high transmission rates when two UEs are located near to each other without obstacles between them. The distribution of UEs is therefore a key factor and consequently, the influence of the density and denseness of UEs to the achievable system performance must be carefully investigated. In a cellular network, D2D communications exploit spatial reuse by offloading mobile traffic. However, the offloading capability varies under different traffic loads and modes. These factors also impact the performance of D2D communications. Moreover, current related works mainly considered network scenarios with static UE distribution. In other words, the issue of mobility has not been fully investigated. Although current researches are meaningful for studying specific cases or snapshots of D2D communications in real-world cellular networks, they did not unveil the impact of user mobility on the achievable system performance. UE mobility not only causes the dynamic changes of network topologies, but also results in frequent change of D2D pairs. Given that 3GPP has recommended several mobility models for performance evaluation [6], it is meaningful and important to evaluate and assess the impact of mobility on D2D performance.

Aiming to address the above problems, we propose a transmission scheduling scheme, termed directional D2D medium access control (D3MAC), for D2D transmissions in mmWave small cells. In a D3MAC enabled cellular system, whenever direct link between the sender and receiver of a flow has high channel quality, the direct transmission will be adopted.
instead of transmission through BSs and backhaul networks. Therefore, the proposed D3MAC fully exploits direct transmissions between devices to improve network performance in terms of throughput and delay. Based on our proposed scheme, we evaluate D2D communication performance in both static and dynamic networks. Specifically, we assess the system performance under different UE density and denseness, traffic loads and modes as well as user mobility, to analyze how these factors affect D2D communications. The contribution of this paper is three-fold, as summarized in the following:

- We formulate the scheduling problem over radio access with direct transmissions between devices into a mixed integer nonlinear program (MINLP), which minimizes the number of time slots to accommodate the transmission demand. Concurrent transmissions, i.e., spatial reuses, are explicitly considered. To solve this problem, we propose an efficient near-optimal scheduling scheme, referred to as D3MAC, which consists of a path selection criterion and a transmission scheduling algorithm. The priority of D2D transmission is characterized by the path selection parameter of the path selection criterion, while concurrent transmissions are fully utilized in the transmission scheduling to maximize the gain of spatial reuse.

- We evaluate the impacts of UE distribution and traffic demand as well as traffic mode jointly on D2D communications underlaying mmWave small cells. Specifically, we observe that generally increasing UE density and denseness benefits D2D communications, but under light traffic loads this improvement is barely observable. In addition, highly erratically arriving traffic flow degrades the D2D performance, especially under heavy traffic loads and with low UE density and denseness. Explanations are given on how these factors affect D2D communications and network performance.

- We carry out the study not only in static networks but also dynamic networks to evaluate the impact of UE mobility on D2D communications. It is observed that the performance is improved under low UE speed, where the mobility enables more D2D pairs to establish, compared to the static case. However, D2D communications perform poorly in high UE mobility networks as a result of the frequent changes of D2D pairs.

This paper is organized as follows. After presenting the related work in mmWave cellular network and D2D communications in Section II, Section III introduces the system model and overview. In Section IV we formulate the scheduling problem for radio access in mmWave small cells, while Section V is devoted to our proposed D3MAC scheme, which includes a path selection criterion and a transmission scheduling algorithm. In Section VI, we demonstrate that D3MAC is able to achieve a near-optimal performance in terms of network throughput and transmission delay. We also evaluate the impact of UE density and denseness as well as traffic load and traffic mode on the performance of D2D communications in static networks. We then involve UE mobility in the discussion and evaluate its impact on the D2D communications in Section VII. We conclude the paper in Section VIII.

II. RELATED WORK

Recently, a number of studies have investigated mmWave technology for cellular networks. Wei et al. [7] discussed six key elements to enable mmWave communications in future 5G networks and addressed some possible approaches. Wu et al. [8] defined and evaluated important metrics to characterize multimedia quality of service (QoS) and designed a QoS-aware scheduling scheme. In terms of small cells in the mmWave bands, most works focused on using bands in 28GHz, 38GHz and 73GHz to attain communication ranges in the order of 200m or even more [9]. Zhu et al. [10] proposed a 60GHz picocell architecture to augment with existing LTE networks for achieving a significant increase in capacity.

We focus on the performance of D2D communications in mmWave cellular networks. By contrast, majority of the existing researches have been conducted on D2D communications in lower frequencies. Lin et al. [6] provided an overview of D2D standardization activities in 3GPP and identified several technical challenges. Qiao et al. [11] proposed an effective resource sharing scheme by allowing non-interfering D2D links to operate concurrently. Although D2D communication may bring enhancement for spectral efficiency, it also causes interference as the result of spectrum sharing. For mmWave D2D communications, current researches have mainly studied the problems of power control [12], resource allocation [13] and interference management [14], [15]. Taking advantage of high propagation loss and the use of directional antennas, D2D links can be supported in mmWave 5G networks to enhance network capacity and improve spectrum efficiency. Instead of just focusing on transmission schemes or power control, we further investigate the factors that have important impacts on D2D communication and evaluate how these factors influence the achievable performance.

Some existing studies have analyzed the performance of D2D communications underlaying systems. Yu et al. [12] evaluated the performance of D2D communication by considering a scenario where only limited interference coordination between the cellular and D2D communications is possible. The works [16], [17] evaluated the D2D systems under different transmission schemes or mode selection mechanisms. These existing works have focused on the scenario of micro-scale cellular networks with lower frequencies. By contrast, we extensively consider the key factors related to user distribution and traffic demand, and investigate their impacts on the performance of D2D communications in mmWave small cells. To the best of our knowledge, there exists no previous study evaluating the influences of user behavior and traffic demands on D2D communications in mmWave small cells.

III. SYSTEM MODEL AND PROBLEM OVERVIEW

A. System Model

Fig. 1 illustrates a typical scenario for dense deployment of mmWave small cells underlying the cellular network. In each small cell, there are several UEs and an access point (AP) which synchronizes the clocks of UEs and provides access services within the small cell. The APs form a mmWave wireless backhaul network, and the backhaul links are optimized in
order to achieve high channel quality and reduce interference. Therefore, we assume that the backhaul links are fixed with optimal scheduling, and we focus on the radio access, where D2D communications are enabled and traffic demands can be transmitted through direct links between nearby UEs instead of through the backhaul network. Some APs are connected to the Internet via high speed wired connections, which are called gateways. The remaining APs must communicate with a gateway in order to send (receive) data to (from) the Internet. To overcome huge path attenuation, both the UEs and APs achieve directional transmissions with electronically steerable directional antennas by the beamforming technique [18].

In the system, there is a centralized controller in the network [19], which usually resides on a gateway. The system resource is partitioned into non-overlapping time slots of equal length, and the controller synchronizes the clocks of APs. Then the clocks of UEs are synchronized by their corresponding APs. There is a bootstrapping program in the system, by which the clocks of UEs are synchronized by their corresponding APs.

In this system, transmissions occur on two types of paths, ordinary and direct paths. A direct path is a direct transmission path from source (a UE) to destination (another UE), which does not pass through the backhaul network. An ordinary path is a transmission path through APs, which may includes the access link from the source to its associated AP, the backhaul path from the source’s AP to the destination’s AP or gateway, and the access link from the destination’s associated AP to the destination. The achievable transmission rates for ordinary paths and direct paths can be obtained via a channel transmission rate measurement procedure [22]. In this procedure, the transmitter of each link transmits measurement packets to the receiver first. Then with the measured signal to noise ratio (SNR) of received packets, the receiver estimates the achievable transmission rate, and determines appropriate modulation and coding scheme by the table related the SNR value with the appropriate modulation and coding scheme.

With directional transmissions, there exists less interference between links. Under low multi-user interference (MUI), concurrent transmissions can be utilized [23]. In the system, all nodes are assumed to be half-duplex, and two adjacent links cannot be scheduled concurrently since each node has at most one connection with one neighbor [24]. We denote the link $i$ from sender $s_i$ to destination $r_i$ by $(s_i, r_i)$, and its transmission rate by $c_{s_i, r_i}$. For two nonadjacent links, we adopt the interference model in [23]. Specifically, for links $(s_i, r_i)$ and $(s_j, r_j)$, the received power from $s_i$ to $r_j$ can be calculated according to

$$P_{r_j, s_i} = f_{s_i, r_j} k_0 P L_{s_i, r_j}^{-\gamma},$$

where $P_0$ is the transmission power that is fixed, $k_0 = 10^{PL(d_0)/10}$ is the constant scaling factor corresponding to the reference path loss $PL(d_0)$ with $d_0$ equal to 1 m, $l_{s_i, r_j}$ is the distance between node $s_i$ and node $r_j$, and $\gamma$ is the path loss exponent [23]. The directional indicator $f_{s_i, r_j}$ indicates whether $s_i$ and $r_j$ direct their beams towards each other. If this is the case, $f_{s_i, r_j} = 1$; otherwise, $f_{s_i, r_j} = 0$. Thus, the desired signal to interference plus noise ratio (SINR) at $r_j$, denoted by SINR$_{s_j, r_j}$, can be calculated according to

$$\text{SINR}_{s_j, r_j} = \frac{k_0 P L_{s_j, r_j}^{-\gamma}}{W N_0 + \rho \sum_{i \neq j} f_{s_i, r_j} k_0 P L_{s_i, r_j}^{-\gamma}},$$

where $\rho$ is the MUI factor related to the cross-correlation of the signals from different links, $W$ is the bandwidth, and $N_0$ is the one-sided power spectra density of white Gaussian noise [23]. For link $(s_i, r_j)$, the minimum SINR to support its transmission rate $c_{s_i, r_j}$ is denoted as $MS(c_{s_i, r_j})$. Therefore, concurrent transmissions can be supported if the SINR of each link $(s_i, r_j)$ is larger than or equal to $MS(c_{s_i, r_j})$.

There are two kinds of flows transmitted in the network, the flows between UEs and the flows from or to the Internet (gateway). We assume there are $N_f$ flows in the network. For flow $i$, its traffic demand is denoted as $d_i$. The traffic demand vector for all the flows is denoted by $d = (d_1, d_2, \ldots, d_{N_f})$, where each element is $d_i$. For each flow, there are two possible transmission paths in the system, ordinary path and direct path. A flow transmitted via an ordinary path is inherently multi hops, while a flow transmitted via a direct path is single hop. For the $l$th hop link of the ordinary path for flow $i$, we denote its sender as $s_{i(l)}^o$ and receiver as $r_{i(l)}^o$, and denote this link as $(s_{i(l)}^o, r_{i(l)}^o)$. We denote the direct link of flow $i$ as $(s_i^d, r_i^d)$, with $s_i^d$ as the source and $r_i^d$ as the destination. If no confusion is caused, the superscripts $o$ and/or $d$ may be dropped.

Let the maximum number of hops of the ordinary paths be $H_{\text{max}}$. Then for each flow $i$, its $1 \times H_{\text{max}}$ transmission-rate vector on the ordinary path is denoted as $c_i^o$, where each element $c_{i(l)}^o$ represents the transmission rate of the $l$th hop. We also denote the $N_f \times H_{\text{max}}$ transmission-rate matrix for the ordinary paths of all flows by $C^o$, whose $ith$ row is simply $c_i^o$. The transmission rate of the direct path for flow $i$ is denoted as $c_i^d$, and the $1 \times N_f$ transmission-rate vector for the direct paths of all flows is denoted as $c^d$, whose $ith$ element is $c_i^d$.

### B. Operation Procedure and Problem Overview

The proposed D3MAC is a frame based medium access control (MAC) protocol similar to the frame-based scheduling directional MAC (FDMAC) of [24]. Each frame consists of a scheduling phase and a transmission phase, and the scheduling overhead in the scheduling phase can be amortized over multiple concurrent transmissions in the transmission phase.
as in the FDMAC of [24]. In the scheduling phase, AP polls its associated UEs successively for their traffic demands and reports to the central controller through the backhaul network. Based on the transmission rates of links, the central controller computes a schedule to accommodate the traffic demands of all flows. Then the central controller pushes the schedule to the APs through the backhaul network and each AP pushes the schedule to its UEs. In the transmission phase, UEs and APs communicate with each other following the schedule until the traffic demands of all flows are accommodated. The transmission phase consists of multiple stages, and in each stage, multiple links are activated simultaneously for concurrent transmissions. In the schedule computation, the transmission path should be selected optimally between the direct path and ordinary path for each flow, and the schedule should accommodate the traffic demands of flows with a minimum number of time slots to fully exploit spatial reuse.

Let us illustrate the basic idea of D3MAC with Fig. 2, where there are three small cells. In cell 1, UEs A and C are associated with AP1, and in cell 2, UE B is associated with AP2, while in cell 3, UE D is associated with AP3. Assume that there are two flows in the network, A→B and C→D. The traffic demands of A→B and C→D are 6 and 8, respectively, and thus d = [6 8]. Numerically, they are equal to the number of packets to be transmitted, assuming that the packet length is fixed. The transmission rate matrix for the ordinary paths of flows obtained by the measuring procedure is

$$C^o = \begin{bmatrix} 2 & 3 & 2 \\ 2 & 4 & 2 \end{bmatrix},$$

which indicates the transmission rates of links A→AP1, AP1→AP2 and AP2→B are 2, 3 and 2, respectively, while the rates of links C→AP1, AP1→AP3 and AP3→D are 2, 4 and 2, respectively. If direct transmission is not enabled, these two flows cannot be scheduled for concurrent transmission due to the half duplex restriction. Thus according to $C^o$ and d, these two flows need 8 and 10 time slots to clear all the traffic demands, respectively, and this will take up 18 slots in total. On the other hand, the transmission rate vector for the two direct paths is measured to be $c^d = [3 2]$. This indicates that the direct link of A→B can transmit 3 packet in one time slot and the direct link of C→D can transmit 2 packet in one time slot.

Clearly, for each flow, we needs to first select the optimal transmission path between its direct path and ordinary path. The optimal schedule should accommodate the traffic demand of flows with a minimum number of time slots. In other words, concurrent transmission should be fully exploited in the schedule. For the example of Fig. 2, the direct links of the both flows should be enabled to enhance performance. According to $c^d$ and d, these two flows need 2 and 4 slots to clear their traffic demands, respectively, and moreover the two direct paths can be scheduled for concurrent transmission since they have no common nodes. Therefore, only 4 time slots are needed in total. This simple example clearly shows that the selection of transmission paths for flows has a significant impact on the efficiency of scheduling and concurrent transmission scheduling should be optimized to improve transmission efficiency, which is the basic idea of the proposed D3MAC.

IV. PROBLEM FORMULATION AND ANALYSIS

A. Radio Access Without Enabling D2D Communications

We begin by formulating the transmission scheduling problem without introducing D2D communications, where the traffics of all flows are transmitted only through ordinary paths. Since there are only ordinary paths, we drop the superscript $o$. Given the traffic demand of flows, to maximize the transmission efficiency, we should accommodate the traffic demand with a minimum number of time slots [24]. Assume that the schedule has $K$ stages, and the number of time slots of the $k$th stage is $\delta_k$, while the duration of a time slot is denoted as $\tau$. The total number of time slots of a schedule is then $\sum_{k=1}^K \delta_k$. For each flow $i$, we define the number of hops for its ordinary path as its hop number $H_i$, and we further define a binary variable $b_{j(i)}^k$ to indicate whether the $j$th hop of the ordinary path for flow $i$ is scheduled to transmit in the $k$th stage. For any two links $(s_i, r_i)$ and $(s_j, r_j)$, we define a binary variable $I(s_i, r_i; s_j, r_j) = 1$; otherwise, $I(s_i, r_i; s_j, r_j) = 0$. In a schedule, if a link is scheduled in one stage, it will transmit as many packets as possible until its traffic demand is cleared. Then, the link will not be active in the remaining slots of this stage. Since concurrent transmissions interfere with each other, the SINR of the $j$th hop of the ordinary path of flow $i$ can be expressed as

$$SINR_{j(i)} = \frac{P_{r_j(i)}s_{j(i)}b_{j(i)}^k}{WN_0 + \rho \sum_u \sum_{v(w(u)\neq j(i))} P_{r_{j(i)}}s_{v(u)}b_{v(u)}^k},$$

where $s_{j(i)}$ and $r_{j(i)}$ denote the transmitter and the receiver of the $j$th hop of the ordinary path for flow $i$. The transmitting rate of link $(s_{j(i)}, r_{j(i)})$ is therefore expressed as

$$c_{j(i)} = \eta W \log_2 \left( 1 + SINR_{j(i)} \right),$$

where $\eta \in (0, 1)$ is the efficiency of the transceiver design.
Regarding the system constraints, first, all traffic demands should be scheduled, which can be expressed as
\[ \sum_{k=1}^{K} \delta_k \tau_{j(i)} c_{j(i)}^k \geq d_i, \forall i \text{ and } j(i) = 1, 2, \cdots, H_i. \] (6)
To avoid frequent beamforming or steering, each link can be activated at most once in a schedule, which means that
\[ \sum_{k=1}^{K} b_{j(i)}^k = \begin{cases} 1, & \text{if } d_i > 0, \\ 0, & \text{otherwise, } \forall i \text{ and } j(i) = 1, 2, \cdots, H_i. \end{cases} \] (7)
Adjacent links cannot be scheduled concurrently in the same stage due to half-duplexing, which can be expressed as
\[ \forall i, j(i), u, v(u), k \text{ and } v(u) \neq j(i) : \]
\[ b_{j(i)}^k + b_{v(u)}^k \leq 1 \text{ if } I(s_{j(i)}^k, r_{j(i)}^k; s_{v(u)}^k, r_{v(u)}^k) = 1. \] (8)
The \( j \)th hop of the ordinary path for flow \( i \) should be scheduled ahead of the \( (j+1) \)th hop, which means that
\[ \forall i, j(i) = 1, 2, \cdots, H_i - 1 \text{ and } K = 1, 2, \cdots, K : \]
\[ \sum_{k=1}^{K} b_{j(i)}^k \geq \sum_{k=1}^{K} b_{j(i+1)}^k \text{ if } H_i > 1. \] (9)
Therefore, the optimal scheduling problem without enabling D2D communications \((P1)\) is formulated as follows:
\[ \min \sum_{k=1}^{K} \delta_k, \] s.t. Constraints \((6)\) to \((9)\) hold. \(B. \) Radio Access with Enabling D2D Communications \]
We now include D2D communications into the scheduling, where each flow can choose using either the original path or the direct path. Define a binary variable \( a_i^k \) to indicate whether the direct link of flow \( i \) is scheduled to transmit in the \( k \)th stage, i.e., if this is the case \( a_i^k = 1 \); otherwise, \( a_i^k = 0 \). The SINRs of the \( j \)th hop of the ordinary path for flow \( i \) and the direct path for flow \( i \) in the \( k \)th stage, denoted by \( \text{SINR}_{j(i)}^o \) and \( \text{SINR}_{j(i)}^d \), respectively, can be expressed as
\[ \text{SINR}_{j(i)}^o = \frac{P_{r_{j(i)}^o s_{j(i)}^o} \cdot b_{j(i)}^k}{WN_0 + \sum_{u \neq j(i)} P_{r_{j(i)}^o s_{u}^o} \cdot b_{u}^k + \rho \sum_{p} P_{r_{j(i)}^o s_{j(i)}^p} \cdot a_{j(i)}^k}, \] (11)
\[ \text{SINR}_{i}^d = \frac{P_{r_{i}^d s_{i}^d} \cdot a_{i}^k}{WN_0 + \sum_{u} P_{r_{i}^d s_{u}^d} \cdot b_{u}^k + \rho \sum_{p} P_{r_{i}^d s_{i}^p} \cdot a_{i}^k}, \] (12)
The transmitting rate of link \( (s_{j(i)}^o, r_{j(i)}^o) \) is therefore given by \( c_{j(i)}^o = \eta WN_0 \log_2 (1 + \text{SINR}_{j(i)}^o) \), while the transmitting rate of link \( (s_{i}^d, r_{i}^d) \) is \( c_{i}^d = \eta WN_0 \log_2 (1 + \text{SINR}_{i}^d) \).
Next let us analyze the system constraints. First, each flow can choose either an ordinary path or a direct path to transmit data, which indicates that
\[ \forall i, k : \sum_{j(i)=1}^{H_i} b_{j(i)}^k = \begin{cases} H_i, & \text{if } a_{i}^k = 0, \\ 0, & \text{if } a_{i}^k = 1. \end{cases} \] (13)
Second, all traffic demands should be scheduled, and hence
\[ \sum_{k=1}^{K} \delta_k \tau_{j(i)} c_{j(i)}^o + c_{j(i)}^d \geq d_i, \forall i \text{ and } j(i) = 1, 2, \cdots, H_i. \] (14)
Each link can be activated at most once in a schedule, which can be expressed as
\[ \sum_{k=1}^{K} b_{j(i)}^k + a_{i}^k = \begin{cases} 1, & \text{if } d_i > 0, \\ 0, & \text{otherwise, } \forall i \text{ and } j(i) = 1, 2, \cdots, H_i. \end{cases} \] (15)
Adjacent links cannot be scheduled concurrently in the same stage, which requires the followings.
\[ \forall i, j(i), u, v(u), k \text{ and } v(u) \neq j(i) : \]
\[ b_{j(i)}^k + b_{v(u)}^k \leq 1 \text{ if } I(s_{j(i)}^k, r_{j(i)}^k; s_{v(u)}^k, r_{v(u)}^k) = 1; \] (16)
\[ \forall i, u, k \text{ and } u \neq i : a_{i}^k + a_{u}^k \leq 1 \text{ if } I(s_{i}^d, r_{i}^d, s_{u}^d, r_{u}^d) = 1; \] (17)
\[ \forall i, u, v(u), k \text{ and } u \neq i : \]
\[ a_{i}^k + b_{v(u)}^k \leq 1 \text{ if } I(s_{i}^d, r_{i}^d, s_{v(u)}^d, r_{v(u)}^d) = 1. \] (18)
To enable concurrent transmissions, the SINR of each link in the same stage should be able to support its transmission rate, which means that for both direct path and ordinary path the followings must hold:
\[ \text{SINR}_{j(i)}^o \geq M S(c_{j(i)}^o \cdot b_{j(i)}^k), \forall i, j(i), k, \] (19)
\[ \text{SINR}_{i}^d \geq M S(c_{i}^d \cdot a_{i}^k), \forall i, k, \] (20)
where \( MS(c_{j(i)}^o) \) denotes the minimum SINR required for the \( j \)th ordinary-path link to support flow \( i \) at the rate \( c_{j(i)}^o \), while \( MS(c_{i}^d) \) is the minimum SINR required for the direct-path link to support flow \( i \) at the rate \( c_{i}^d \). Lastly, the constraint \((9)\) is still required.
Therefore, the problem of optimal scheduling \((P2)\) where D2D communications are enabled is formulated as follows:
\[ \min \sum_{k=1}^{K} \delta_k, \] s.t. Constraints \((9)\), \((13)\) to \((20)\) hold.
By solving Problem \( P2 \), we can obtain the optimal scheduling solution for the network, which minimize the slots needed for transmissions. However, Problem \( P2 \) is an MINLP as some of the constraints in \( P2 \) are nonlinear constraints.

V. THE D3MAC SCHEME

It is computationally unacceptable to use an exhaustive search to solve Problem \( P2 \) for practical networks with mmWave small cells where the duration of a time slot is only a few microseconds. Therefore, we opt for a heuristic algorithm with low complexity to obtain a near-optimal solution so that the scheduling scheme can be implemented in practice. We solve this MINLP by two steps. At the first step, we select an appropriate transmission path, either a direct path or an ordinary path, for each flow. If the direct path has high channel quality and can achieve higher transmitting capability than the ordinary path, we choose the direct transmission. At the second step, we accommodate the traffic demand of flows with as few time slots as possible by making full use of every slot and enabling concurrent D2D links as many as possible.
A. Path Selection Criterion

For flow $i$, let $p_i^d$ denote its direct path and $p_i^o$ denote its ordinary path. For the direct transmission path $p_i^d$ with the transmission rate $c_{p_i^d}$, we define its transmission capability as

$$A(p_i^d) = c_{p_i^d}. \quad (22)$$

Further assume that the ordinary path $p_i^o$ has $H_{\text{max}}$ hops, and the transmission rate of its $j$th hop is $c_{j}^o(p_i^o)$. We can define transmission capability of the ordinary path $p_i^o$ as

$$A(p_i^o) = \frac{1}{H_{\text{max}} \sum_{j=1}^{H_{\text{max}}} \frac{1}{c_{j}^o(p_i^o)}}. \quad (23)$$

For each flow $i$, we choose the path with higher transmission capability between its direct path and ordinary path. Therefore, the path selection criterion can be expressed as

$$\forall i : \begin{cases} \text{if } \frac{A(p_i^o)}{A(p_i^d)} \geq \beta, & \text{choose } p_i^d, \\ \text{otherwise,} & \text{choose } p_i^o, \end{cases} \quad (24)$$

where $\beta \geq 1$ is the path selection parameter. The smaller $\beta$, the higher the priority of direct transmissions between devices.

Algorithm 1: Path Selection

1. Input: Sets $P^d_i$ and $P^o_i$.
2. Output: The set of selected paths for all the flows $P$.
3. Initialization: $P = \emptyset$.
4. For each flow $i$ do
   5. Obtain $A(p_i^d)$ and $A(p_i^o)$;
   6. if $\frac{A(p_i^o)}{A(p_i^d)} \geq \beta$ then
      7. $P = P \cup p_i^d$;
   8. else
      9. $P = P \cup p_i^o$;
10. Return $P$.

The pseudocode of the path selection process is presented in Algorithm 1, where $P^d$ and $P^o$ denote the sets of all potential paths $p_i^d$ and $p_i^o$, respective, while the set $P$ contains all the selected paths for all the flows.

B. Heuristic Transmission Scheduling Algorithm

We propose a heuristic transmission scheduling algorithm to accommodate the traffic demand of flows with as few time slots as possible by fully exploiting spatial reuse. In order to manage the interference effectively by choosing proper hops for concurrent transmissions, we introduce a contention graph to depict the contention relationship between hops. In the contention graph, each vertex represents a hop in the network, and there is an edge between two vertices if there exists severe interference between these two hops. For hop $l$ and hop $j$, we define the maximum interference between them as

$$\omega_{l,j} = \max \{ P_{r_j, s_l}, P_{r_l, s_j} \}. \quad (25)$$

To control the interference, we set a threshold $\alpha_{l,j}$, and the contention graph is constructed in the way that if the maximum interference between two vertices is less than the threshold, i.e., if $\omega_{l,j} < \alpha_{l,j}$, there will be no edge between these two vertices. Otherwise, there will be an edge between them. There is always an edge between any two adjacent hops since they cannot be scheduled for concurrent transmissions due to the half-duplex assumption. We denote the contention graph by $G(V, E)$, where $V$ denotes the set of vertices in the contention graph, and $E$ denotes the set of edges in the contention graph.

We refer to two vertices as neighbors if there is one edge between them in the contention graph. For any vertex $v \in V$, we denote the set of its neighboring vertices by $N(v)$. We further define the weight of vertex $v$ as the number of time slots that the hop $v$ needs for transmission, denoted by $W_v$.

The pseudo-code of our transmission scheduling algorithm is presented in Algorithm 2. To manage the interference between concurrent transmitting hops, hops with an edge between them in the contention graph should not be scheduled in the same time. Hence, we first obtain all the hops that can be scheduled currently at stage $k$ and build the contention graph (lines 6 and 7), based on the which we schedules the unscheduled hops of flows iteratively in non-increasing order of weight with the conditions for concurrent transmissions satisfied (lines 8 to 19). In line 11, a hop in $H_u^k$ can either

Algorithm 2: Heuristic Transmission Scheduling

1. Input: The set of selected paths for all the flows in stage $k$, denoted by $P^k$.
2. Output: $\{ H_u^k \}_{u=1}^{\delta_k}$, $\delta_k$.
3. Initialization: Obtain the set of all the hops in $P^k$; $u = 0; \delta_k = 0$;
4. While $|H| > 0$ do
   5. $u = u + 1; |H_u^k| = |H|; \delta_u^k = 0$;
   6. Obtain all the hops that can be scheduled currently into the set $H$;
   7. Obtain $G_u^k(V_u^k, E_u^k)$ based on $H$;
   8. While $|H| > 0$ do
      9. Obtain $v \in V_u^k$ with the largest weight $W_v$;
      10. $H_u^k = H_u^k \cup v$;
      11. For each hop $(s_{i(j)}, r_{i(j)})$ in $H_u^k$ do
          12. Obtain $\text{SINR}_{s_{i(j)}, r_{i(j)}}$;
          13. if $\text{SINR}_{s_{i(j)}, r_{i(j)}} < MS(c_{i(j)})$ then
              14. $H_u^k = H_u^k \setminus v$;
              15. Go to line 18;
      16. $c_u^k = \max \{ c_{u^k}, \lfloor \frac{1}{|H_u^k|} \rfloor \}$;
      17. $H_H = H_H \setminus N(v)$;
      18. $H = H \setminus v$;
      19. Obtain $G_u^k(V_u^k, E_u^k)$ based on $H$;
      20. $\delta_u^k = \delta_u^k + c_u^k$;
      21. $H_u^k = H_u^k \setminus H_u^k$;
      22. $U^k = u$;
      23. Return $\{ H_u^k \}_{u=1}^{\delta_{k}}$.
be a hop of an ordinary path or a link of a direct path, and we have draped the corresponding superscript $o$ or $d$. Also if it is a direct link, we have $\delta(j) = i$. In line 16, ⌊⌋ is the integer floor operator. In this inner loop, scheduling is stopped when no possible hop can be scheduled concurrently any more. The algorithm carries out this process iteratively until all the hops of all the flows considered in stage $k$ are properly scheduled (lines 4 to 21). In the output of the algorithm, $U^k$ is the maximum number of hops for the longest multi-hop flow scheduled at stage $k$, and for $1 \leq u \leq U^k$, $\mathcal{H}_u^k$ contains the hops or links that are scheduled for concurrent transmissions, while $\delta^k$ is the number of time slots required for $\{\mathcal{H}_u^k\}_{u=1}^{U^k}$. Note that if $n$ denotes the number of UEs in the network, the number of concurrent transmission links should be no more than $\lfloor n \rfloor$ [24], due to the non-adjacent constraint.

VI. Static Network Evaluation and Analysis

A. Comparison with Optimal Solution and Other Protocols

Under a static network environment, we first give an extensive performance evaluation for our proposed D3MAC scheme, given various traffic patterns. Specifically, we compare its performance with those of the optimal solution, obtained by solving the problem $P_2$ with YALMIP [25], and some existing protocols. In the simulation, the transmission rate $R$ between UEs as well as between UEs and associated APs is set to 2 Gbps, 4 Gbps and 6 Gbps, respectively, according to the distances between devices. Due to better channel qualities, the transmission rate of backhaul links is set to 6 Gbps. With $R = 2$ Gbps, a packet can be transmitted in one time slot. The packets with transmission delay larger than the delay threshold $\vartheta$ are declared as unsuccessful transmissions and discarded. Generally, the central controller is able to complete traffic polling, schedule computation and schedule pushing in a few time slots. Two traffic modes, the Poisson process (PP) and interrupted PP (IPP), are used in the performance evaluation.

a) PP packets arrive at each flow following the Poisson process with arrival rate $\lambda$. The traffic load, denoted by $T_{load}$, in a PP traffic is defined as

$$T_{load} = \frac{\lambda \cdot L \cdot N_f}{R},$$  

where $L$ is the size of data packets.

b) IPP packets arrive at each flow following the IPP with the parameters $\lambda_1$, $p_1$, $\lambda_2$ and $p_2$. The arrival intervals of the IPP obey the second-order hyper-exponential distribution with a mean of

$$E(X) = \frac{p_1}{\lambda_1} + \frac{p_2}{\lambda_2}. \quad (27)$$

The traffic load $T_{load}$ in this case is defined as

$$T_{load} = \frac{L \cdot N_f}{E(X) \cdot R}. \quad (28)$$

The achievable system performance is assessed by the following two metrics.

i) Average Transmission Delay: The average transmission delay of the received packets from all the flows, and we evaluate it in units of time slots.

ii) Network Throughput: The total number of the successful transmissions of all the flows over the duration of the simulation. For each received packet, if its delay is less than or equal to the threshold $\vartheta$, it is counted as a successful transmission.

Fig. 3. Comparison with the optimal solution under Poisson traffic.

Fig. 3 compares the achieved throughput and delay performance by the proposed D3MAC with those of the optimal solution under Poisson traffic, where it can be observed that the performance gap between the D3MAC and the optimal solution is negligible. Even under the traffic load of 2.8, the D3MAC only increases the average transmission delay by less than 10% and reduces the network throughput by less than 3%, compared to the optimal solution. We point out that by optimizing the path selection parameter $\beta$, the performance gap between the D3MAC and the optimal solution can be further reduced. The results of Fig. 3 therefore demonstrate that the D3MAC achieves a near-optimal performance.

2) Comparing with other protocols: Next we compare the D3MAC with the following three benchmark schemes.

i) ODMAC. In the ordinary directional MAC (ODMAC) [24], [26], [27], D2D transmissions are not enabled, and all the flows are transmitted through their ordinary paths. The scheduling algorithm of the ODMAC is the same as that used in the proposed D3MAC. This benchmark scheme represents
the current state-of-the-art in terms of scheduling the access or backhaul without considering D2D transmissions.

ii) **RPDMAC**. The random path directional MAC (RPDMAC) [18] selects the transmission path for each flow randomly from its direct path and ordinary path. Its scheduling algorithm is the same as that of the D3MAC. Thus, the RPDMAC is a good benchmark scheme to show the advantages of the path selection criteria in the D3MAC.

iii) **FDMAC-E**. This is an extension of the FDMAC [24], and to the best of our knowledge, the FDMAC achieves the highest efficiency in terms of spatial reuse. In the FDMAC-E, the transmission path is selected in the same way as the D3MAC with the path selection parameter $\beta = 2$. However, in order to show the role of backhaul optimization, the access links and backhaul links are separately scheduled in the FDMAC-E. The access links from UEs to APs are scheduled by the greedy coloring (GC) algorithm of the FDMAC [24]. The backhaul links on the transmission path are scheduled by the time-division multiple-access (TDMA). The access links from APs to UEs are also scheduled by the GC algorithm.

![Network throughputs as functions of traffic load achieved by the four schemes under Poisson traffic.](image)

The network topology is the same as used in obtaining the results of Fig. 3. The simulation duration is set to 0.5 s, and the delay threshold $\rho$ is set to $10^4$ time slots, while the rest of the simulation parameters are as listed in Table I. Fig. 4 compares the network throughputs as functions of traffic load for the four protocols under the PP traffic. It can be seen from Fig. 4 that under the light load from 0.5 to 1.5, all the four schemes achieve similar performance. The performance of the ODMAC protocol degrades considerably when the traffic load increases beyond 1.5, and it attains the worst performance. The RPDMAC protocol only begins to degrade when the network load increases beyond 2, and it outperforms the ODMAC scheme which confirms that enabling D2D transmissions improves the network throughput. For the FDMAC-E protocol, the rate of increase in the throughput begins to reduce as the load becomes larger than 2, and its throughput becomes saturated around 400,000 for high traffic load, which is significantly larger than those of the RPDMAC and ODMAC schemes. The proposed D3MAC protocol attains the best performance. Specifically, the throughput of the D3MAC increases linearly with the traffic load. At the high load of 5, the achievable network throughput of the D2MAC is 56% higher than that of the FDMAC-E.

**B. Performance Evaluation in Static Networks**

We now evaluate the impact of UE behaviors. A typical dense deployment of mmWave small cells is simulated, where 9 APs, i.e., 9 small cells, are uniformly distributed in a square area of $50 \times 50$ m and the gateway is located at the center of the area. We concentrate on investigating the influences of the UE density and the UE denseness, under different traffic loads and different traffic modes, on the achievable system performance.

1) **Influence of UE density**: To evaluate how the density of UEs influences D2D communications, we deploy 20, 30, 40, 50 and 60 UEs uniformly in the area, which makes the average density 0.008, 0.012, 0.016, 0.020 and 0.024 UE/m$^2$, respectively. Each UE is associated with the nearest AP. 30 flows are set in the simulation, 20 of which are between UEs, while 10 of which are between UEs and the gateway, including uploading and downloading. Other simulation parameters are identical to those used in obtaining the results of Fig. 4.

![Network throughput as the function of UE density attained by the D3MAC, given different traffic loads.](image)

Fig. 5 depicts the network throughputs as the function of the UE density by the D3MAC with three different traffic loads, while Fig. 6 shows the network throughputs as the function of the traffic load with 5 different UE densities, under both the PP and IPP traffics. We observe that basically, the network throughput increases with the density of UEs as well as with the traffic load but the impact of the UE density is heavily influenced by the traffic load and vice versa.

More specifically, it can be seen from Fig. 5 (a) that when the UE density is very low, the achievable throughputs are similar under all the three PP traffic loads, and additionally increasing the UE density has the same positive impact for all the three cases of traffic loads. However, for the relatively light traffic load of 3, when the traffic load exceeds 0.012 UE/m$^2$, the network throughput becomes saturated. Also, the throughput increase in the case of traffic load 3.5 becomes slower when the traffic load exceeds 0.016 UE/m$^2$. By contrast, the rate of the throughput increase with the traffic load of 5
actually increases when the UE density exceeds 0.016 UE/m². Similarly, as can be seen from Fig. 6 (a), under light traffic loads, the network throughput increases with the traffic load, and this trend is independent of the UE density. When the traffic load exceeds certain critical value, which is different for different UE densities, the throughput starts to grow slowly and eventually becomes saturated under heavy loads. The exception is the very high UE density case of 0.024 UE/m², where the network throughput keeps increasing with the traffic load. The throughputs of the IPP-traffic network given in Fig. 5 (b) and Fig. 6 (b) show the same trends of the PP-traffic network but the system under IPP traffic attains slightly lower throughput than the PP-traffic network, which is caused by less stable arrival of IPP packets.

It can be seen that the influence of the UE density and traffic load on the achievable network throughput is highly complicated. The UE density has significant impact on D2D communication in heavily loaded systems, and high UE density increases the system throughput greatly. Increasing the UE density may also increase the throughput performance of D2D communication under light loads, but the improvement is less obvious and smaller. High UE density increasing system throughput can be explained as follows. The average distance between UEs decreases as the number of UEs increases in the network, which improves the channel qualities between UEs and increases the transmission rates of D2D links. This allows more flows to transmit packets through D2D links instead of ordinary paths, leading to a higher throughput. However, this impact on throughput is heavily dependent on the traffic load. The increase of throughput brought by high UE density is more profound under heavy traffic loads. This is because in a heavily loaded system, the network may originally be unable to transmit all packets within the delay threshold. By increasing the UE density, these originally unsuccessful transmissions can be transmitted successfully through more and better D2D links. Under light loads, on the other hand, the network is originally able to transmit almost all packets within the delay threshold, and there is less need to relying on the improvement brought by high UE density for increasing successful transmissions. Thus the UE density has less impact on light-load networks.

Fig. 7 shows the average transmission delays as the function of the UE density obtained by the D3MA with three different traffic loads, while Fig. 8 depicts the average transmission delays as the function of the traffic load with five different UE densities. We can clearly see that the transmission delay is reduced as the UE density increases, while the transmission delay increases with the network traffic load. We also observe that the average transmission delay performance of the IPP-traffic network is worse than that of the PP-traffic network, since the IPP traffic has lower arriving stability than the PP traffic and this erratically arriving traffic demand causes longer waiting time at the transmitting devices’ queues and hence longer transmission delay.

The reason that the transmission delay decreases as the UE density increases is simple. With the increase of the UE density, the transmission opportunities increases and this reduces the waiting time of the packets to be transmitted. In addition, a higher UE density also improves the channel quality, which improves the successful transmission rate and reduces re-transmissions. This also helps improving the transmission delay performance. The reason that increasing the traffic load worsens the transmission delay performance is also obvious. Increasing the network traffic load simply means more packets to be transmitted, which increases the packets’ waiting time in the transmission queues of the transmitting devices, leading to a higher transmission delay.

2) Influence of UE denseness: The denseness of UEs is another important factor that affects the performance of D2D communication. With a fixed UE density, high UE denseness indicates that UEs are distributed unevenly, and low denseness means that UEs are near-uniformly distributed. In order to find out how the UE denseness impacts on D2D communication, we deploy the same simulated network with the UE density fixed to 0.016 UE/m². However, in each small cell, the locations of UEs follow the two-dimensional normal distribution with the mean at the cell center and the standard deviation $\zeta$ per dimension. The denseness of UEs can be adjusted by changing the value of $\zeta$, where a small $\zeta$ indicates a large UE denseness and vice versa. We set the levels of UE denseness from 1 to 5, which correspond to the values of $\zeta$ equal to 20, 18, 16, 14, 12, and 10.

Figs. 9 and 10 show that the network throughput and average transmission delay achieved by the D3MAC as the functions of UE denseness, respectively, given three different traffic loads. The results of Fig. 9 indicate that the throughput increases with UE denseness. Given the UE density, distances between UEs in high denseness systems become shorter and, therefore, the channel qualities are improved. However, for light-load systems, the throughput stops increasing after the UE denseness reaches certain level. By contrast, for heavy-load networks, the throughput keeps increasing with a similar rate. Under heavy loads, the traffic demand is beyond the transmitting capability.
of the original system. Thus higher UE denseness improves the performance by increasing transmission rates. One of the other hand, in a lightly loaded system, the traffic demand may almost be met by the transmitting capability of the original system, and there is less need to rely on the increase of UE denseness for improving transmission rates. Similarly, the average transmission delay is reduced as the UE denseness increases, due to the increase in the transmission rates. Furthermore, the transmission delay decreases more rapidly as the UE denseness increases, under heavy loads. This rapid reduction in transmission delay as the UE denseness increases under heavy loads is mainly due to the large reduction of the packets’ waiting time. By contrast, such an effect is small and not so obvious under light loads. The results of Figs. 9 and 10 also show that the performance of the PP-traffic network is better than that of the IPP-traffic network.

The complicated coupling influences of the traffic load and UE denseness on the performance of D2D communication are further illustrated in Figs. 11 and 12, which depict the network throughput and average transmission delay as the functions of the traffic load, respectively, with different levels of UE denseness. Again, we observe that under light loads, the average transmission delay is very small. When the traffic load exceeds certain value, which is different for different levels of UE denseness, the transmission delay begins to increase rapidly. Also under light loads, the network throughput increases with the traffic load. When the traffic load exceeds certain value, which again is different for different levels of UE denseness, the throughput grows slower and eventually becomes saturated.

3) **Influence of traffic mode:** As have shown about, the performance of the PP-traffic network is better than that of the IPP-traffic network, because the IPP packets has lower arriving stability than the PP packets. We now have a closer look into the impact of the traffic mode as well as its coupling influence with other network key parameters. Specifically, Fig. 13 shows the network performance as the function of traffic load under PP and IPP traffics and with different UE densities, while Fig. 14 illustrates the network performance as the function of traffic load under PP and IPP traffics and with different levels of UE denseness. We can clearly observe that the PP-traffic system outperforms the IPP-traffic system, in terms of achieving higher throughput and lower transmission delay. Moreover, the impact caused by traffic mode varies with traffic
load, UE density and UE denseness. The performance gap between the two systems is larger under heavy traffic load, low UE density and low UE denseness.

VII. Dynamic Network Evaluation and Analysis

The distribution of UEs is usually dynamic in real world networks and the dynamic changes of the network topology have profound impact on the achievable performance. In order to evaluate the impact of user mobility on the performance of D2D communication, we adopt the realistic human mobility model SLAW proposed by Brockmann et al. [28] in our simulation, where the distribution of user traveling distance decays at a power law with the parameter $\lambda_{\text{decay}}$, and the probability of user remaining in a small, spatially confined region for a time period $T_{\text{stay}}$ is dominated by algebraically long tails that attenuate with the super diffusive spread. UEs are initially distributed uniformly with the UE density equal to 0.016 UE/m$^2$ and their mobility traces are generated by the random walk model. Other simulated network parameters remain the same as before. Based on the scale of the simulated network, we set $\lambda_{\text{decay}} = 0.2$, which makes the average moving distance of UE 5 m, and the mean value of $T_{\text{stay}}$ is set to 1 s. In order to schedule the system with the D3MAC, we consider the network topology and UE locations static within a rather short duration of time, which is 0.1 s in the simulation, and the transmission rates of all links are updated every 0.1 s. Since the speed of UE is one of the key factors that determines the network topology, we evaluate the throughput and delay performance of the system under different UE velocities to unveil the impact of UE mobility.

From the the above results and analysis, we can draw the conclusion that low UE speed improves the performance of D2D communication, in terms of throughput and transmission delay, due to the establishment of new D2D links. When the average UE speed exceeds certain value, the system performance suffers considerably owing to the frequent change of network topology, which results in highly unstable D2D links. This detrimental effect is further amplified by heavy traffic load.

VIII. Conclusions

In this paper, we have investigated the optimal scheduling problem of radio access of small cells in the mmWave band that enables D2D communications and fully utilizes the spatial reuse. Because the optimal solution for this scheduling problem is computationally prohibitive for large-scale networks, we have proposed a centralized MAC scheduling scheme, referred to as the D3MAC, to solve this scheduling problem efficiently. Through extensive simulations, we have demonstrated that the D3MAC achieves a near-optimal performance, in terms of network throughput and transmission delay, and it outperforms the random walk model.
other existing protocols. Our other main contribution has included a comprehensive evaluation of how the user behavior impacting the achievable D2D communication performance in the network consisting of mmWave small cells, based on our proposed D3MAC protocol. Specifically, we have carefully investigated the five key factors related to user behavior, namely, UE density, UE denseness, UE mobility, traffic load and traffic mode. Our study has unveiled intriguing patterns and complex interactions of these factors in influencing the achievable performance of D2D communications in mmWave small cells. Our results and observations thus offer valuable lessons and useful guidelines in designing future networks of mmWave based small cells.
