Maternal smoking during pregnancy
Path analyses

ABSTRACT

*Background:* Low birth weight and gestational maternal smoking have been linked with reduced lung function in children in many cross sectional studies. However, these associations have not yet been assessed with repeated measurements of lung function. Our aim was to investigate the effects of birth weight, gestational age, and gestational maternal smoking on lung function in children at age 10 and 18 years.

*Methods:* In the Isle of Wight birth cohort spirometry was performed at age 10 and 18 years. Information on birth weight and gestational age were obtained from hospital records. Mothers were asked about smoking during pregnancy. We employed linear mixed models to estimate the effect of these risk factors on repeated measurements of lung function. We considered maternal asthma, sex, neonatal intensive care unit admission, height, socio-economic status, personal smoking in participants at age 18, body mass index and environmental tobacco smoke exposure as potential confounders. Finally, we used path analysis to determine links between birth weight, gestational age and gestational maternal smoking on lung function at age 10 and 18 years.

*Results:* Linear mixed models showed that with every 1 kg increase in birth weight, Forced expiratory volume in one second ($FEV_1$) increased by 42.6 ± 17.2 mL and Forced expiratory flow between 25% and 75% ($FEF_{25-75}$) of Forced vital capacity (FVC) increased by 95.5 ± 41.2 mL at age 18 years after adjusting for potential confounders. Path analysis suggested that birth weight had positive direct effects on $FEV_1$ and $FEF_{25-75}$ and positive indirect effect on FVC at 10 years which were carried forward to 18 years. Additionally, results also suggested a positive association between gestational age and $FEV_1$, FVC and $FEF_{25-75}$ at ages 10 and 18 years and an inverse association between gestational smoke exposure and $FEV_1$/FVC ratio and $FEF_{25-75}$ at age 18 years.

*Conclusions:* Higher birth weight and gestational age were associated with higher $FEV_1$, FVC and $FEF_{25-75}$ and maternal smoking during pregnancy was associated with reduced $FEV_1$/FVC ratio and $FEF_{25-75}$. The use of path analysis can improve our understanding of underlying "causal" pathways among different prenatal and childhood factors that affect lung function in both pre-adolescent and adolescent periods.

## 1. Introduction

The 'Barker hypothesis' also known as 'fetal origins of adult disease' hypothesis, states that adverse exposures encountered during intrauterine life can result in permanent changes in physiology which may result in increased risk of chronic diseases in adulthood [1]. Barker et al. showed that, fetal and infant growths

http://dx.doi.org/10.1016/j.rmed.2016.10.010

are associated with lung function in adults and low birth weight (LBW) may increase the risk of death from chronic obstructive lung disease [2]. Other studies have also shown that LBW and very low birth weight (VLBW) are associated with reduced lung function in children [3–7]. Two more studies have found a positive relationship between continuous birth weight measures and lung function in children [8,9]. In adults, the findings are mixed, some studies reported a significant positive linear trend between birth weight and lung function [10–13], while other studies found no association [14].

The process of lung development begins in the intrauterine period and continues well into late adolescence/early adulthood. Therefore, intrauterine exposures affecting lung development during fetal life, for example maternal smoking, may have a long term negative impact on lung function. Additionally, maternal smoking during pregnancy is known to result in pre-term births and LBW in full term babies [15,16]. Thus, maternal smoking during pregnancy, gestational age and birth weight are correlated and birth weight may be in the pathway between *in-utero* exposure to maternal smoking and lung function. However, there is disagreement on whether maternal smoking during pregnancy has independent effect on reduction of lung function in childhood [17–19]. Previous studies while investigating association between birth weight and lung function have adjusted for the effect of maternal smoking during pregnancy without addressing the fact that birth weight may be an intervening variable. Similarly, height which is a significant determinant of lung function may also act as an intervening variable in the path between birth weight and lung function as many pediatric studies have shown a positive association between birth weight and growth of height during childhood [20,21].

Lung function during childhood and adolescent periods is determined by complex relationships between several factors that need to be taken into account simultaneously. However, adjusting for intervening variables as confounders not only distorts the causal pathway but also leads to an over-adjustment bias [22]. The inconsistent results in association between birth weight and lung function in the above mentioned studies may be attributed to the use of traditional regression analyses, which do not take into consideration the directional or non-directional relationships between various observed factors. To elucidate these complex relationships, use of path analysis provides a novel approach. A variable representing the response in one equation can act as a risk factor in another equation, thus allowing the inclusion of intervening or mediating variables in the model. Finally, simultaneously solving multiple linear regression equations generates direct, indirect and total effects of each variable on the outcome, which can be used to develop a causal path diagram.

To gain better understanding of the relationship between birth weight, maternal smoking, and lung function in children at age 10 and 18 years, we analyzed data from the Isle of Wight (IOW) birth cohort. We explored these associations first by using linear regression, followed by linear mixed models and path analysis in which we assessed complex relationships between different prenatal and childhood factors that may affect the association between birth weight and lung function.

## 2. Materials and methods

### 2.1. Study population

Between January 1989 and February 1990, 1536 mothers/child pairs were contacted to be enrolled in the IOW birth cohort. After obtaining informed written consent 1456 were enrolled and available for follow-up at 1, 2, 4, 10 and 18 years of age. Among them, 1121 children were tested for spirometry either at 10 ($n = 981$) or 18 years of age ($n = 838$) or both ($n = 698$) The IOW cohort is described in detail elsewhere [23–25].

### 2.2. Birth weight and other measurements

Information on birth weight, gestational age, and admission to neonatal intensive care unit (NICU) were obtained from the hospital records. Information on maternal smoking during gestation, sex of the child, and maternal history of asthma was ascertained after delivery. We considered maternal smoking during gestation, maternal history of asthma, sex, admission to NICU, height, socioeconomic status (SES), personal smoking in children at age 18, body mass index (BMI) and environmental tobacco smoke (ETS) exposure at age 10 and 18 as potential confounders or intervening variables. Information on the SES was based on the following three variables: (a) the British socioeconomic classes (1–6) derived from parental occupation reported at birth; (b) the number of children in the index child's bedroom (collected at age 4 years); and (c) family income at age 10 years [25]. Height and weight were measured before spirometric tests at age 10 and 18 years; BMI was calculated. To address the differential growth pattern in height in boys and girls we considered an interaction term between height and sex. Exposure to ETS at age 10 and 18 was inquired from questions of “any smoking in the household”. Active smoking at age 18 years was ascertained from the study participants at age 18.

### 2.3. Lung function

Lung function tests were conducted at 10 and 18 years of age. Forced vital capacity (FVC), Forced expiratory volume in one second ($FEV_1$), Forced expiratory flow between 25% and 75% of FVC ($FEF_{25-75}$) and Peak expiratory flow rate (PEFR) were measured using a Koko Spirometer and software with a portable desktop device (both PDS Instrumentation, Louisville, KY, USA). Spirometry was performed and evaluated according to the American Thoracic Society (ATS) criteria. Children were required to be free of respiratory infection for two weeks and not to be taking any oral corticosteroids and were advised to abstain from any β-agonist medication for six hours and from caffeine intake for at least four hours [23].

### 2.4. Statistical analysis

Firstly, to determine effects of birth weight and maternal smoking during pregnancy on lung function at cross-sectional level we used standard linear regression technique separately at ages 10 and 18 years. Next, we used linear mixed models for repeated measurements on cohort of children who were tested for lung function either at age 10 or18 years or both. Unstructured covariance structure matrix was selected based on lowest Akaike information criteria and the Bayesian Schwarz information criterion after considering unstructured, compound symmetry and autoregressive covariance structure matrices. All models were adjusted for above mentioned confounders. The models assessing the relationship between maternal smoking *in-utero* and lung function and gestational age and lung function were not adjusted for birth weight. We selected the confounders that changed the estimates of main exposures (birth weight, exposure to *in-utero* maternal smoking and gestational age) by 10%. We also included an interaction term between sex and height since the relationship between height and lung function varies by sex [26]. To control for type-I error due to multiple comparisons the significance level was set at alpha = 0.025 whenever interaction term between height and sex was included in the model. Otherwise significance level of alpha = 0.05 was maintained for rest of the models.

To address the issue of missing data on one or more confounders we used multiple imputations to generate ten new datasets. All datasets were analyzed separately for both linear regressions and linear mixed models. Finally all results were combined and valid statistical inferences were generated using MIANALYZE.

### 2.5. Path analysis

As mentioned earlier birth weight and height act as intervening variables on two separate pathways from maternal smoking during pregnancy and lung function and linear mixed models do not address the issue of intervening variables. Adjusting on these variables may lead to biased estimates. Therefore, we explored the relationships between birth weight, maternal smoking during pregnancy and lung function at age 10 and 18 years by linear path analysis using Covariance Analysis of Linear Structural Equations. Since data on covariates was missing completely at random we used Full Information Maximum Likelihood (FIML) method to determine parameter estimates. The adequacy of model fit was determined by several statistics: a Chi-square p-value > 0.05 for the difference between the theoretical and the empirical model, comparative fit index (CFI) > 90, adjusted goodness of fit index (GFI) > 90 and root mean square error of approximation (RMSEA) < 0.06. The data were analyzed using the SAS statistical package (version 9.3; SAS Institute, Cary, NC, USA).

## 3. Results

There were no significant differences between full IOW cohort and the sample of participants who were tested for lung function at either age [Table 1]. In total 1121 children had spirometry tests done either at age 10 years (n = 981) or 18 years (n = 838) or both (n = 698). The average birth weight was 3.4 ± 0.5 kg and 22.7% children were exposed to maternal smoking *in-utero*.

### 3.1. Linear regression at age 10 and 18 years of age

At 10 years of age, with every 1 kg increase in birth weight there was a significant increase in $FEV_1$, FVC and $FEF_{25-75}$ [Table 2]. There was also a significant increase in $FEV_1$/FVC ratio with every one week increase in gestational age but no significant effect of maternal smoking during pregnancy on lung function at age 10 years. At 18 years of age, birth weight showed a positive association with $FEV_1$ and FVC and those who were exposed to maternal smoking *in-utero* had an increase in FVC and hence significant decrease in $FEV_1$/FVC ratio.

### 3.2. Linear mixed models

Results from linear mixed models (repeated measurements) showed that with every 1 kg increase in birth weight, $FEV_1$ and $FEF_{25-75}$ increased by 42.6 ± 17.2 mL and 95.5 ± 41.2 mL, respectively at age 18 years [Table 3]. The models were adjusted for maternal smoking during pregnancy, sex, height, age, gestational age, maternal history of asthma, admission to NICU, smoking at 18 years of age and the interaction between height and sex. We found no effect of maternal smoking during pregnancy or gestational age on any lung function parameters.

### 3.3. Path analysis

Figs. 1 and 2 illustrate statistically significant direct effects (path coefficients) of each factor on $FEV_1$ and $FEF_{25-75}$, respectively. Detailed information on direct and indirect effect of each factor on lung function parameter is provided in the online supplement. In Fig. 1, path coefficients suggested a positive direct effect of birth weight on $FEV_1$ at age 10, but no direct effect at age 18 years. However, since $FEV_1$ at age 10 years has a positive direct effect on $FEV_1$ at age 18 years presumably the effect of birth weight on $FEV_1$ at age 10 was carried forward (indirect effect) to age 18 years as indicated by a positive total effect (direct + indirect) of birth weight on $FEV_1$ at 18 years (Table 2 in online supplement). On the other hand, maternal smoking during pregnancy had no significant direct or indirect effects on $FEV_1$ either at age 10 or 18 years (Tables 1 and 2 in online supplement); however, it may have an inverse indirect effect on $FEV_1$ through reduction in birth weight. Additionally, gestational age also had positive indirect and total effects on $FEV_1$ both at ages 10 and 18 years (Tables 1 and 2 in online supplement).

Fig. 2 shows that birth weight had a positive direct effect on $FEF_{25-75}$ at age 10, which was carried forward to age 18 years. Another significant finding was that of a direct negative effect of exposure to maternal smoking *in-utero* on $FEF_{25-75}$ at age 18 years but not at age 10 years which was not seen in $FEV_1$. Gestational age also had a positive indirect effect on $FEF_{25-75}$ at age 10 years but not at age 18 years (Tables 1 and 2 in online supplement). We also found that birth weight had a positive indirect effect on FVC at age 18 years and exposure to maternal smoking *in-utero* had a positive direct effect on FVC and therefore negative direct effect on the $FEV_1$/FVC ratio (Table 2 in online supplement).

## 4. Discussion

We studied the IOW birth cohort to assess the association between birth weight and gestational smoking on lung function at 10 and 18 years. Using linear mixed models for repeated measurements we found that there was significant increase in $FEV_1$ and $FEF_{25-75}$ with every 1 kg increase in birth weight at age 18 years after adjusting for potential confounders. We did not find any significant association of maternal smoking during pregnancy with lung function after adjusting for other potential confounders. The results of the linear path analysis were different from the linear mixed models. Path analysis showed that birth weight had positive effects not only on $FEV_1$and $FEF_{25-75}$ but also on FVC either directly or indirectly through various pathways. Additionally, path analysis also showed that maternal smoking during pregnancy had direct negative associations with the $FEV_1$/FVC ratio (due to increase in FVC) and $FEF_{25-75}$ and that gestational age was positively linked with $FEV_1$ and FVC through birth weight.

### 4.1. Relationship between birth weight and lung function in children

Most previous studies assessing relationship between birth weight and lung function conducted in children focused on investigating effects of LBW and VLBW on respiratory health, since these are well-known risk factors for increased morbidity and mortality in infants. Findings from these studies showed that children born with LBW and VLBW children had significantly lower lung function [3,7] and volumes [6,27] along with increased bronchial hyperresponsiveness [7] when compared to normal birth weight. However, approaches using dichotomized birth weight do not provide information on whether there is linear relationship between birth weight and lung function. Rona et al. investigated the association between continuous birth weight and lung function and demonstrated a positive linear association between birth weight adjusted for gestational age and $FEV_1$ and FVC at age 10 years in children of 5–11 years of age [8]. Our findings showing a positive association between birth weight and $FEV_1$ and FVC are consistent with those of Rona et al. However, in contrast to our results, Rona et al. did not find any significant association between birth weight and $FEF_{25-75}$.

**Table 1**
Comparison of baseline characteristics for children with spirometry either at age 10 or 18 with total IOW cohort.

Sonnenschein et al. examined the association of children's growth pattern with asthma and lung function [9] and found that at 8 years of age higher birth weight was strongly associated with higher FVC, $FEV_1$ and $FEF_{25-75}$ *z*-scores and at age 15 years with higher FVC and reduced $FEV_1$/FVC and $FEF_{25-75}$/FVC ratios [9]. Our findings from linear regression models at age 10 years are comparable to those of Sonnenschein et al. at 8 years. However, our results using appropriate models for repeated measurements, such as linear mixed

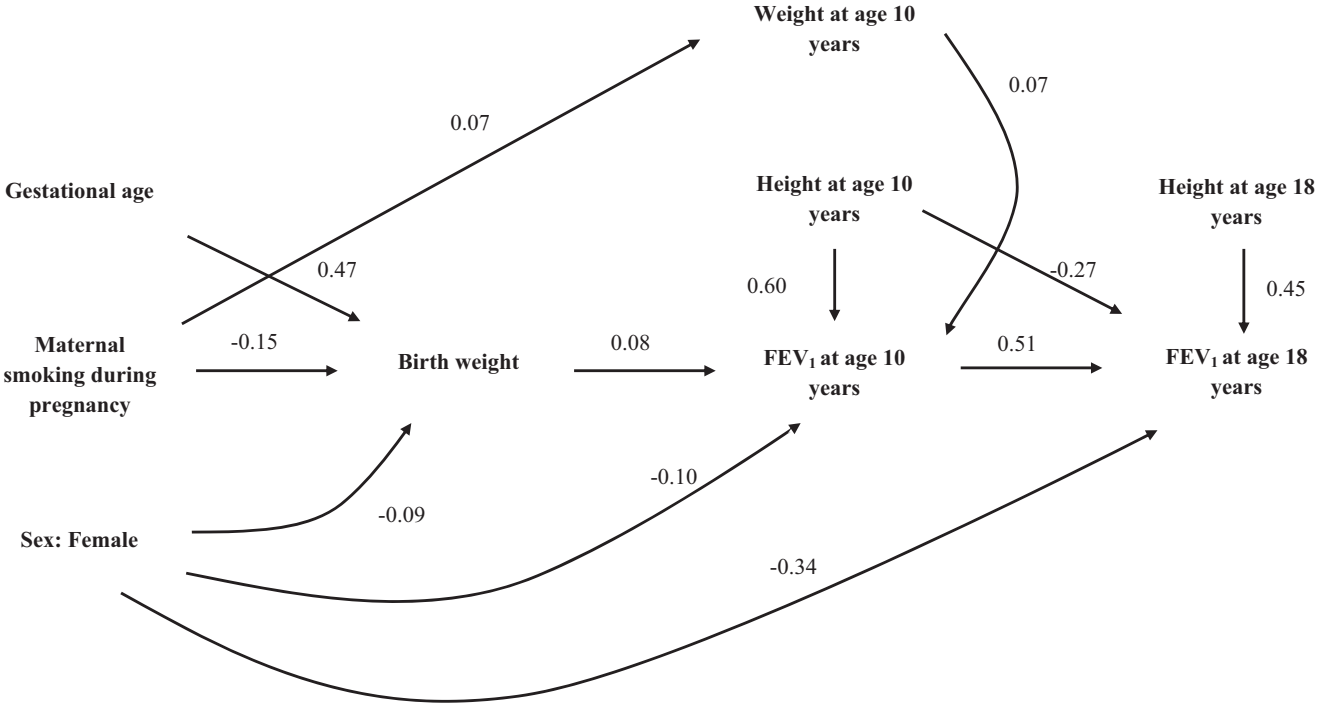

**Fig. 1.** Path diagram - association of birth weight, gestational age and gestational maternal smoking with $FEV_1$. This analytical path diagram shows statistically significant standardized direct effects (path coefficient) of birth weight, gestational age and maternal smoking status during pregnancy on $FEV_1$ at 10 and 18 years.

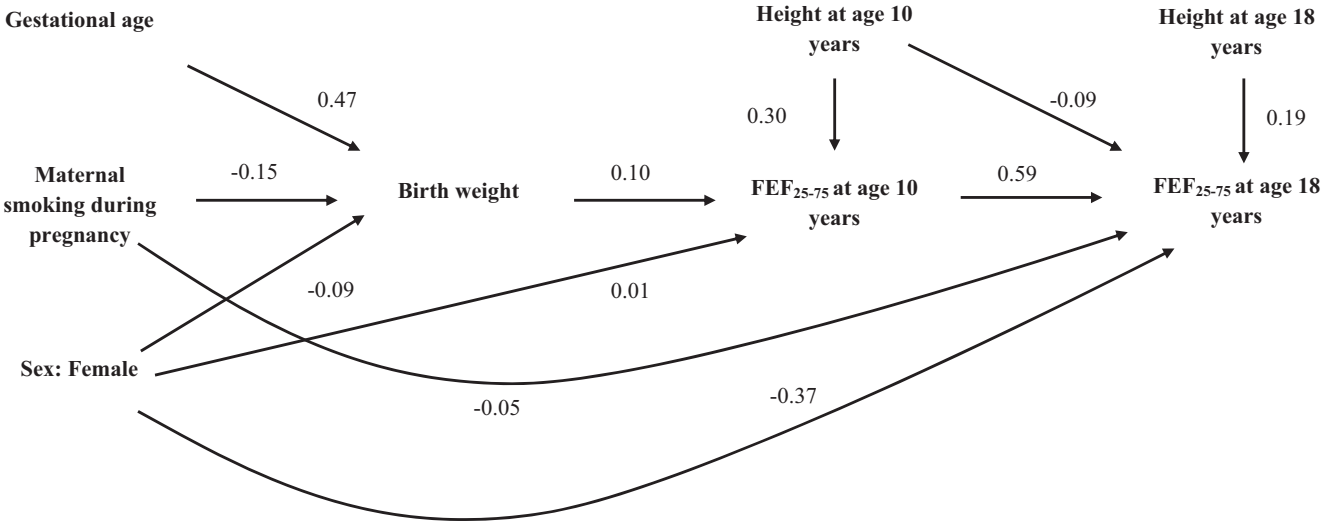

**Fig. 2.** Path diagram - association of birth weight, gestational age and gestational maternal smoking with $FEF_{25-75}$. This analytical path diagram shows statistically significant standardized direct effects (path coefficient) of birth weight, gestational age and maternal smoking status during pregnancy on $FEF_{25-75}$ at 10 and 18 years.

models and path analysis, showed that birth weight also had positive association with $FEV_1$ and $FEF_{25-75}$ in addition to FVC, at age 18 years.

### 4.2. Relationship between maternal smoking during pregnancy, gestational age, birth weight and lung function: path analysis

The results from previous studies exploring the relationship between maternal smoking during pregnancy and lung function are mixed. Some studies have suggested reduction in lung function in children exposed to maternal smoking *in-utero* [17,28] while other studies reported no such association [19,29]. While most studies have not adjusted for birth weight in their statistical models, Hayatbakhsh et al. found a reduction in lung function in boys of age 21 years even after adjusting for birth weight [30]. One can argue that birth weight and maternal smoking are in the same 'causal pathway' related to intra-uterine growth retardation and both should not be used in the same model. In these situations, use of traditional analysis does not allow to discern the independent effects of risk factors (maternal smoking and birth weight) on the outcome (lung function). In standard regression analysis each variable is identified as either risk or effect prior to analysis and statistical relationship between these variables are based on a conditional expected value. These models do not take into consideration the temporal sequence and thus are ill-suited for modeling relationships which are composed of effects mediated through intervening variables. Linear path analyses on the other hand accommodate intervening variables in the analysis [31]. Using path analysis, we found that exposure to maternal smoking *in-utero* was associated directly with reduction in $FEF_{25-75}$ and increase in FVC. These findings were not evident in linear mixed models. Additionally, path analysis also showed that even though birth weight did not have any significant direct effect on FVC at age 18 years it did have significant indirect effect [Table 2 online supplement].

One of the main findings of our study was the positive association between birth weight and $FEF_{25-75}$ at age 18 years which measures airflow in small airways; this association was not shown by Sonnenschein et al. in adolescents of age 15 years [9]. Birth weight is a surrogate marker for intrauterine growth and gestational age and maternal smoking during pregnancy have significant adverse effect on birth weight. Hence the association between birth weight and lung function may reflect the underlying association between gestational age and maternal smoking during pregnancy with lung function. Previous studies have shown that higher gestational age was associated with higher $FEF_{25-75}$ [9] and maternal smoking during pregnancy was associated with reduced $FEF_{25-75}$ [17,28,30]. Our path analysis results are consistent with these findings [Fig. 2]. The underlying patho-physiological mechanisms are not fully understood. Although histopathological studies have shown that broncho-pulmonary dysplasia, a hallmark of respiratory distress syndrome in premature babies, is characterized by formation of hyaline membrane in small airways, enlargement and oversimplification of alveoli and increase in interstitial thickening leading to a reduction in elastic recoil [32,33]. Additionally, an animal model presented by Rehan et al. to study the effects of maternal smoking on fetal lung development showed that *in-utero* exposure to tobacco smoke alters the normal homeostatic epithelial-mesenchymal interaction in the developing alveolus, resulting in production of myofibroblasts in larger as well as smaller airways, which is a common finding in asthma and chronic lung disease [34].

Our results from cross-sectional analysis at age 18 years (Table 2) and path analysis (Table 2 in online supplement) showed a positive association between maternal smoking and higher FVC, comparable to the previous studies, which have also shown an association between maternal smoking during pregnancy and higher FVC in children [26,35,36]. Studies have suggested that maternal smoking during pregnancy or exposure to parental smoking during early childhood may cause disproportional growth of lung parenchyma and airways known as dysynaptic growth of lungs in children [35,37–39].

One of the major limitations of this study is that the information on smoking during pregnancy was self-reported and was not verified by objective measurements like urine cotinine levels. Studies have shown that self-reported smoking status during pregnancy grossly underestimates the true prevalence of smoking during pregnancy [40,41]. Therefore, it is likely that the prevalence of smoking during pregnancy in our study is underestimated which may in turn bias our findings related to maternal smoking and lung function towards null. The second important limitation of this study was that there was a lack of information on number of cigarettes smoked per day and duration of smoking by mothers during pregnancy. Therefore, we were not able to assess the dose-response relationship between in-utero exposure to smoking and lung function.

The strength of this study is that we analyzed lung function measurements in pre-adolescents and adolescents, thus covering an important period of lung development. In addition, cohort members who participated in lung function testing were not different from the participant of the overall birth cohort. To our knowledge no other study has investigated the risk of gestational and neonatal conditions on lung function in the adolescence with repeated measurements and path-analytical models. As information on birth weight, gestational age and maternal smoking during pregnancy were recorded soon after birth; a recall bias is unlikely. To address a few missing information, multiple imputations were used. This is a robust method to overcome the problem of missing data and to generate unbiased estimates. We also used linear mixed models which were more appropriate than simple linear regression models as they also consider individual change in lung function across time. Use of path analysis allowed us to include intervening variables in models whose inclusion in linear mixed models would normally produce biased estimates.

## 5. Conclusions

In conclusion, we found that higher birth weight was significantly associated, either directly or indirectly, with higher $FEV_1$, FVC and $FEF_{25-75}$ in adolescents at age 18 years. Though we did not find significant associations between maternal smoking and lung function through standard linear mixed models, the more appropriate path analysis showed that gestational smoke exposure does have negative effects on $FEV_1$/FVC ratio due to increase in FVC and on $FEF_{25-75}$ at age 18 years. With path analysis, we gained insight and better understanding about the underlying links between various prenatal and early childhood factors that affect lung function. Our results suggest that the beneficial effects of favorable fetal growth, which is reflected by birth weight, goes beyond lung function changes in early childhood years. Future research investigating effects of gestational smoking, birth weight and growth on lung function should consider employing path analyses models to disentangle the complex relationships between these determinants of lung function.

## Funding

This study is funded by the National Institute of Health (NIH) R01 AI091905 (principle investigator W. Karmaus). The 10-yr follow-up of this study was funded by National Asthma

Campaign, UK (grant no. 364) and the 18-yr follow-up by NIH R01 HL082925 (principle investigator S.H. Arshad).

## Author's contributions

WK and SHA was involved in the design of the study, development, and preparation of data. PB under the guidance of WK analyzed data and wrote the first draft of the manuscript. WK, SHA, GR, RK, FM and SB discussed data analyses and interpretation and contributed to subsequent versions of the manuscript. All authors read and approved the final manuscript.

## Competing interests

None declared.

## Acknowledgements

The authors gratefully acknowledge the cooperation of the children and parents who participated in this study, and appreciate the hard work of the Isle of Wight research team in collecting data.

## List of abbreviations

| | |
|---|---|
| LBW | Low birth weight |
| VLBW | Very low birth weight |
| IOW | Isle of Wight |
| NICU | Neonatal intensive care unit |
| SES | Socio-economic status |
| BMI | Body mass index |
| ETS | Environmental tobacco smoke |
| FVC | Forced vital capacity |
| $FEV_1$ | Forced expiratory volume in one second |
| $FEF_{25-75}$ | Forced expiratory flow between 25% and 75% of forced vital capacity |
| PEFR | Peak expiratory flow rate |
| ATS | American Thoracic Society |
| FIML | Full information maximum likelihood |
| CFI | Comparative fit index |
| GFI | Goodness of fit index |
| RMSEA | Root mean square error of approximation |

## Appendix A. Supplementary data
