Gravitational waves were discovered with the detection of binary black hole mergers¹ and they should also be detectable from lower mass neutron star mergers. These are predicted to eject material rich in heavy radioactive isotopes that can power an electromagnetic signal called a kilonova^{2,3,4,5}. The gravitational wave source GW170817 arose from a binary neutron star merger in the nearby Universe with a relatively well confined sky position and distance estimate⁶. Here we report observations and physical modelling of a rapidly fading electromagnetic transient in the galaxy NGC4993, which is spatially coincident with GW170817

and a weak short gamma-ray burst^{7,8}. The transient has physical parameters broadly matching the theoretical predictions of blue kilonovae from neutron star mergers. The emitted electromagnetic radiation can be explained with an ejected mass of $0.04 \pm 0.01 M_{\odot}$ with an opacity of $\kappa \leq 0.5 \text{ cm}^2 \text{ g}^{-1}$ at a velocity of $0.2 \pm 0.1c$. The power source is constrained to have a power law slope of $\beta = -1.2^{+0.3}_{-0.3}$, consistent with radioactive powering from r-process nuclides. We identify line features in the spectra that are consistent with light r-process elements ($90 < A < 140$). As it fades, the transient rapidly becomes red, and emission may have contribution by a higher opacity, lanthanide-rich ejecta component. This indicates that neutron star mergers produce gravitational waves, radioactively powered kilonovae, and are a nucleosynthetic source of the r-process elements.

The Advanced LIGO and Advanced Virgo experiments^{9, 10} detected gravitational wave emission (called GW170817) on 2017 Aug 17 12:41:04 UT (MJD 57982.528524)⁶ from the merger of two in-spiralling objects consistent with being a neutron star binary. The source and initial skymap was announced to the collaborating follow-up groups at 2017 Aug 17 13:08:17 UT. The small sky area of 33.6 square degrees of the 90% probability contour in the combined LIGO and Virgo analysis (in the LALInference map^{11, 12}) prompted us to plan to tile the region with our Pan-STARRS program to search for electromagnetic counterparts of gravitational wave sources. However, given the low elevation and report of a transient discovery¹³ in a galaxy within the volume constrained by LIGO-Virgo (released at 2017 Aug 18 01:05:23 UT)¹³, we changed strategy to gather early multi-colour photometry of the source called SSS17a¹³ and DLT17ck¹⁴ by the two teams, and formally registered with an IAU name of AT2017gfo. We began imaging the source at 2017 Aug

18 05:33 UT with Pan-STARRS1 and then took our first spectrum under the extended Public ESO Spectroscopic Survey for Transient Objects (ePESSTO¹⁵) on 2017 Aug 18 23:20 UT. We started photometric monitoring with GROND on 2017 Aug 18 23:56 UT providing combined photometry across the optical and infra-red bands, $UgrizJHK_s$ (Figure 1 and Extended Data Figure 1 and Methods).

Before GW170817, we had monitored this sky area with ATLAS¹⁶ between 2015 Dec 12 15:50 UT and 2017 Aug 01 06:19 UT observing a total of 414 images, typically with 4-5 images per night. No transient or astrophysical variability was detected at the position in ATLAS difference images to 5σ limits of $o = 18.7$ and $c = 19.3$ mag (see Methods and Extended Data Figure 2). The ATLAS pre-discovery limits show that it is unlikely that AT2017gfo is a transient in NGC4993 which is not physically associated with GW170817 and is merely a chance coincidence. We assume that AT2017gfo is an unusual, supernova-like explosion in NGC4993 that exploded within 16 days of GW170817. The number of supernovae expected within the four-dimensional space (volume and time) defined by the LIGO distance range for GW170817, (73 Mpc, the 3σ limit⁶) and within the 90% sky area of 33 square degrees, and within 16 days is $n_{\text{SN}} = 0.005$, assuming a supernova rate¹⁷ of $R_{\text{SN}} = 1.0 \times 10^{-4} \text{ Mpc}^{-3} \text{ yr}^{-1}$. It is unlike any known nearby, or distant, supernova (see Extended Data Figures 1 and 3). If we assume that the rate of events similar to AT2017gfo is $\sim 1\%$ of the volumetric supernova rate (see Methods Section) then the probability of a chance coincidence in space and time is $p = 5 \times 10^{-5}$ (equivalent to 4σ significance).

We calculated a bolometric lightcurve and total luminosity emitted assuming a distance to

NGC4993 of $d = 40 \pm 4$ Mpc and appropriate Galactic foreground extinction (see Methods section for details of the calculation). In Figure 2 we compare the absolute magnitude of AT2017gfo in all bands to several kilonova models calculated for NS-NS mergers predicted before this discovery. All models are powered by radioactivity of r-process elements (β -decays, α -decays and fission)² formed in the merger. The set includes both simple and advanced radiative-transfer treatments, and they differ in their treatment of the opacity of the ejected material. Each of the models predict fast-fading red transients, with some variation in luminosity and decline rate. If heavy lanthanides (atomic masses $A > 140$) dominate the ejecta then the opacity is predicted to be high^{3,4}, with the inevitable consequence of a longer duration, infra-red transient as seen in Figure 2 for the Barnes et al.¹⁸ and the Tanaka & Hotokezaka⁴ lanthanide rich models. These models do reproduce the near infra-red luminosity at 7 - 14 days but the observed early emission which is hot and blue is not reproduced in merger models which are dominated by heavy lanthanide composition. The Metzger model¹⁹ can produce a “blue kilonova” by using a lower opacity, appropriate for light r-process elements (a blend of elements with $90 < A < 140$). This model has a grey opacity and a thermalization efficiency²⁰ is assumed. The slope of the ejecta velocity distribution α is defined such that the amount of mass travelling above velocity v scales as $M(> v) = M_0(v/v_0)^{-\alpha}$. This gives a good fit to the data, suggesting that very high opacities, which block much of the optical light are not applicable in the first 3 - 4 days or depend on orientation¹⁹. A minimum velocity value $v_{ej} \simeq 0.1 c$ is preferred, which within current simulation uncertainties is similar to both dynamic and wind ejecta²⁰. We assess this is more likely a wind component as these can more easily obtain low opacity (see Methods Section).

We further explore the “blue kilonova” scenario by calculating our own quantitative models based on the semi-analytic methods of Arnett²¹, extended to adopt a general term for powering^{22, 23} and Metzger¹⁹. For the Arnett model, we used a power law for the power term with absolute scaling (decay per energy per gram per second) after 1 day as obtained in radioactivity models¹⁹ with a free exponent β (such that $P \propto t^\beta$). The other parameters are ejected mass M_{ej} , energy E (or equivalently velocity v_{ej} as defined by $\frac{1}{2}M_{\text{ej}}v_{\text{ej}}^2 = E$) and opacity κ . As κ and E are fully degenerate (as κ/\sqrt{E}) when trapping is not explicitly coupled (as here), we effectively fit over M_{ej} , β and κ/v_{ej} . The best fits are shown in Figure 3. With no other constraints except that we enforce $v_{\text{ej}} < 0.2c$, the best fitting models have $M_{\text{ej}} = 0.02 \pm 0.01 M_\odot$, $\kappa = 0.1 \times \left(\frac{v_{\text{ej}}}{0.2c}\right) \text{ cm}^2 \text{ g}^{-1}$ and $\beta = -1.5^{+0.3}_{-0.2}$. If we also implement a thermalization efficiency^{20, 19} to account for efficiency of the powering mechanism to provide heat to the ejecta, the values change to $M_{\text{ej}} = 0.04 \pm 0.01 M_\odot$, $\kappa = 0.1 \times \left(\frac{v_{\text{ej}}}{0.2c}\right) \text{ cm}^2 \text{ g}^{-1}$ and $\beta = -1.2^{+0.3}_{-0.3}$ (see Extended Data Figures 4,5 for probability density plots of the parameters).

The mass and power law exponent are remarkably close to predicted kilonova values. In particular, β has been shown to be robustly between -1.3 and -1.2 for r-process radioactivity, with weak sensitivity to electron fraction and thermodynamic trajectory^{2, 24, 25}. We find the data can be explained with a low mass of ejecta having opacity consistent with a blend of elements in the $90 < A < 140$ mass range powered by r-process radioactive decays. Our models interpret the first three data points as the end of the diffusion phase, and match the later points with the early tail phase (starting at 2 - 3 days).

Many previous kilonova models predict that if heavy r-process elements such as the lanthanides and actinides are produced then high opacities of around $\kappa = 10 \text{ cm}^2 \text{ g}^{-1}$ would be likely^{4, 20}. In Figure 3 we show the best fits forcing $\kappa = 10 \text{ cm}^2 \text{ g}^{-1}$. No model with this high opacity is able to fit all the data points well, but it can fit the later data points. In these high-opacity models all observations are still within the diffusion phase, but a steeper power law for energy input ($\beta \simeq -2$) is favoured to produce the right emergent luminosity, no longer consistent with $t^{-1.3}$. If our reconstructed bolometric light curve is accurate at all epochs, there is not much room for a second component at later times as the blue one cannot drop faster than the power source term. However, its possible that 2-component SED fitting would give somewhat different late time bolometric estimates. Then a two-component model where the early light curve is produced by a low-opacity ejecta (a wind component), and the later by a high-opacity one (dynamic ejecta) could also be possible. The early blue flux is unlikely to be from a relativistic jet²⁶ and an afterglow from the weak gamma ray signal that was detected^{7, 8}, due to the rapid reddening and cooling and the X-ray non-detections.

The optical and NIR spectra support the ejecta being dominated by the light r-process elements at least at early stages. We have used the TARDIS code²⁷ to construct simple models to guide interpretation of our spectra. Our earliest NTT spectrum (epoch +1.4 day) is fairly well parameterised by a black-body of $T_{\text{eff}} = 5200 \text{ K}$, and does not show the prominent spectral features (Ca, Mg or Si) commonly detected in normal supernova spectra (see Extended Data Figure 3). There are two broad and blended structures at 7400 \AA and 8300 \AA , respectively, which become stronger in the subsequent spectra. We have extended the TARDIS atomic database to include

lines of elements with atomic number $31 < Z < 60$ (or $60 < A < 140$) from the Kurucz atomic line list²⁸, although the available atomic data for these heavy elements is of limited quality and quantity. We propose the broad feature at 7000–7500 Å is from neutral Caesium ($A = 133$), and is the $6s\ ^2S \rightarrow 6p\ ^2P$ resonance doublet ($\lambda\lambda 8521, 8943$) at a photospheric velocity of $\sim 0.15 - 0.20c$ (see Figure 4). Our model predicts no other strong features of Cs I in the observed region, which could be used to confirm (or refute) this identification. For the redder absorption, we can identify an intriguing potential match with the Tellurium ($A = 128$) $5p^3(^4S)6s\ ^5S \rightarrow 5p^3(^4S)6p\ ^5P$ triplet of Te I. This moderate-excitation multiplet could plausibly be excited at the temperature in our model and would produce absorption around 8000–8500 Å. Reliable oscillator strengths for this multiplet are not available in the NIST atomic spectra database²⁹, but we included it in our TARDIS spectral model by adopting $\log gf = 0$ for each member of the triplet. This illustrates a broadly consistent match with the velocity and thermal conditions that correspond to the Cs I identification. The ionized states (Cs II and Te II) are predicted to dominate by mass, meaning that our model can not provide reliable elemental mass estimates (see Methods Section for more details). The second spectrum covering 0.35–2.2 μm further indicates that Cs I and Te I are plausible candidates. The photospheric velocity adopted in TARDIS (0.2 c for the +1.4 d spectrum) is roughly consistent with that used in our light-curve model at this phase. We further checked atomic data line-lists for possible light r-process elements³⁰ in this range, finding neutral and singly ionized Sb, I and Xe transitions. The Xe I lines align well with possible absorption features seen around 1.48 and 1.75 μm in our +4.4 day spectrum, along with Cs I and Te I features. However, in our TARDIS models, the excitation energies of the relevant Xe I states are too high to make lines of this ion an

important contributor at the temperatures considered, unless it is non-thermally excited.

The light curve and spectra of this fast-fading transient are consistent with an ejecta being high velocity, low mass, and powered by a source consistent with the r-process decay timescales. We can fit the full lightcurve with relatively low-opacity material consistent with the light r-process elements. We can't rule out that a second component consisting of the heavy lanthanides and actinides contributes to the infra-red flux after 3 days. Orientation effects of the dynamic ejecta and wind may play a role in what is observed ¹⁹. This shows that the nucleosynthetic origin of the r-process elements³¹ can be in neutron star mergers.

Author Contributions SJS is PI of ePESSTO, co-lead for Pan-STARRS GW follow-up, led writing of text and managed project. AJ wrote the lightcurve fitting code, led the modelling and co-wrote the text. MC provided code for modelling and MCMC, provided analysis and text, and KW provided input. SAS, LJS and MM did the TARDIS modelling, assisted by AG-Y in line identification. T-WC, JG, SK, AR, PS, TS, TK, PW and ANG managed, executed, reduced and provided GROND data. EK, MF, CI, KM, TK and GL reduced and analysed photometry and spectra and contributed to analysis, text and figures. KWS and DRY ran data management for ATLAS and Pan-STARRS analysis. JT is ATLAS lead and provided data. KCC is Pan-STARRS director, co-lead of GW follow-up and managed the observing sequences. Pan-STARRS and ATLAS data and products were provided by the team of MEH, JB, LD, HF, TBL, EAM, AR, ASBS, BS, RJW, CW, HW, MW and DEW. CWS is ATLAS co-lead for GW follow-up and contributed to text. OMB and PC checked the ATLAS data for candidates and OMB provided manuscript editing support. The ePESSTO project was delivered by the following, who have contributed to data, analysis and text comments: RK, JDL, DSH, CA, JPA, CRA, CA, CB, FEB, MB, MB, ZC, RC, AC, PC, AdC, MTB, MDV, MD, GD, NE-R, REF, AF, AF, CF, LB, SG-G, MG, CPG, AH, JH, KEH, AH, M-SH, STH, IMH, LI, PAJ, PGJ, ZK-R, MK, MK, HK, AL, IM, SM, JN, DON, FO, JTP, AP, FP, GP, MLP, SJP, TR, RR, AJR, KAR, IRS, MS, JS, MS, FT, ST, GT, JV, NAW, LW, OY, GC and AR. PP provided text and analysis comments. The 1.5B telescope data were provided, reduced and analysed by LH, AM-C, LS, HS and BvS. AM reduced and analysed the NACO and VISIR data.

Figure 1: | **Observational data summary** **a:** The position of AT2017gfo lying within the Ligo-Virgo skymap^{11, 6} **b:** Color composite image of AT2017gfo from GROND on 20170818 (MJD 57983.997), 1.45 days after GW170817 discovery. The transient is $8.50''$ North, $5.40''$ East of the centre of NGC4993, an S0 galaxy at a distance of 40 ± 4 Mpc. This is a projected distance of 2 kpc. The source is measured at position of RA=13:09:48.08 DEC= $-23:22:53.2$ J2000 ($\pm 0.1''$ in each) in our Pan-STARRS1 images. **c:** ATLAS limits between 40 and 16 days before discovery (orange filter), plus the Pan-STARRS1 and GROND r and i -band light curve. **d:** Our full light curve data, which provides a reliable bolometric light curve for analysis. Upper limits are 3σ and uncertainties on the measured points are 1σ .

Figure 2: | **Light curves of AT2017gfo.** The combined photometry and five kilonova models^{4, 32, 18, 19, 33} predicted before this discovery. From Barnes et al.¹⁸, we use a model with $M_{\text{ej}} \approx 5 \times 10^{-2} M_{\odot}$ and $v_{\text{ej}} \approx 0.2c$. From Kasen et al.³², we use the $t300$ disk wind outflow model corresponding to a simulation where the resultant neutron star survives 300 ms before collapsing to a black hole. From Tanaka & Hotokezaka⁴, we use a model of a binary neutron star merger with masses 1.2 and 1.5 M_{\odot} assuming the APR4 equation of state, resulting in $M_{\text{ej}} \approx 9 \times 10^{-3} M_{\odot}$. From Wollaeger et al.³³, we include a model with $M_{\text{ej}} = 0.005 M_{\odot}$ and $v_{\text{ej}} = 0.2c$. From Metzger¹⁹, we use a model with $M_{\text{ej}} \approx 5 \times 10^{-2} M_{\odot}$, $v_{\text{ej}} \approx 0.2c$, $\alpha = 3.0$, and $\kappa_r = 0.1 \text{ cm}^2 \text{ g}^{-1}$.

Figure 3: | **Model light curve fits using the Arnett formalism.** Mass, velocity, opacity (κ) and a power-law slope for radioactive powering (β) are freely variable. Each of these parameters were allowed to vary to give the best fit (reduced χ^2 are quoted). **a:** The blue solid line shows the best fit. The green dashed model includes also a thermalization efficiency¹⁹. The recovered power law ($\beta = -1.0$ to -1.3) is close to the one predicted in kilonova radioactivity models ($\beta = -1.2$). **b:** Best fits when opacity is forced to $\kappa = 10 \text{ cm}^2 \text{ g}^{-1}$, to all data (blue, solid) and excluding first three data points (green, dashed). In all models the maximum allowed velocity is $0.2 c$, which is also the preferred fit value. The errors are 1σ uncertainties on the data, while the later points after 10 days are uncertain due to systematic effects. The full MCMC analysis and uncertainties are discussed in the Methods section.

Figure 4: | **Spectroscopic data and model fits** **a:** Spectroscopic data from +1.4 to +4.4 days after discovery, showing the fast evolution of the SED. The points are coeval *UgrizJHK* photometry. **b:** Comparison of the +1.4 day spectrum with a TARDIS spectral model that includes Cs I and Te I [see text]. Arrows indicate the positions of spectral lines blueshifted by 0.2 c, corresponding to the photospheric velocity of the model (the adopted black-body continuum model is also shown for reference). **c:** The Xshooter spectrum at +2.4 days, also shows Cs I and Te I lines that are consistent with the broad features observed in the optical and near infra-red (here, the lines are indicated at velocities of 0.13 c and we include additional, longer wavelength transitions to supplement those in B.).

Methods

Distance and Reddening The host galaxy NGC4993 has been identified as a member of a group of 10 galaxies (LGG 332)³⁴. The heliocentric recessional velocity of $2951 \pm 26 \text{ km s}^{-1}$, or $z = 0.009843 \pm 0.000087$, is from optical data³⁵. The kinematic distance (correcting for various infall models and using $H_0 = 71 \pm 2 \text{ km s}^{-1} \text{ Mpc}^{-1}$) and the Tully Fisher distances to the group containing NGC4993³⁶ are in good agreement within the uncertainty of $d = 40 \pm 4 \text{ Mpc}$ (distance modulus $\mu = 33.01 \pm 0.20$), and we adopt this value. The foreground reddening values in the direction of NGC4993 and AT2017gfo (as reported in NED¹) are adopted to be $A_U = 0.54$, $A_g = 0.39$, $A_r = 0.28$, $A_i = 0.21$, $A_z = 0.16$, $A_y = 0.13$, $A_J = 0.09$, $A_H = 0.06$, $A_K = 0.04$ (Landolt U , Pan-STARRS1 $grizy_{P1}$ and UKIRT JHK), or $E(B - V) = 0.11 \text{ mag}$. These reddening corrections were applied to the photometry to calculate absolute magnitudes and bolometric luminosities.

Hubble Space Telescope pre-discovery data NGC4993 was observed by the Hubble Space Telescope using the Advanced Camera for Surveys (ACS) Wide Field Channel on 2017 April 28, less than four months prior to the discovery of AT2017gfo. $2 \times 348 \text{ s}$ exposures were taken with the F606W filter (comparable to Sloan r'). As this is the deepest image of the site of AT2017gfo taken prior to discovery, we examined it for any possible pre-discovery counterpart.

We localised the position of AT2017gfo on the ACS image by aligning this to the GROND i' images taken on each of the nights from 2017 Aug 18 to 21. Nine point sources common to

¹The NASA/IPAC Extragalactic Database (NED) is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

both the GROND and ACS images were matched, and the final position on the ACS image has an uncertainty of 28, 50 mas in x and y respectively, determined from the scatter among the positions as measured on different GROND images.

No sources were detected by the DOLPHOT³⁷ photometry package at a significance of 3σ or higher, within a radius $> 3\times$ the positional uncertainty. We determined the limiting magnitude at the position of AT2017gfo to be $F606W > 27.5$ (VEGAMAG), based on the average magnitude of sources detected at 3σ within a 100×100 pixel region centred on the position of AT2017gfo. For our adopted distance modulus and foreground reddening, this implies that any source at the position of AT2017gfo must have an absolute magnitude $F606W > -5.8$.

ATLAS system and observational data and upper limit to the rate of kilonova events The Asteroid Terrestrial-impact Last Alert System (ATLAS)³⁸, is a full-time near Earth asteroid survey. It is currently running two 0.5 m f/2 wide-field telescopes on Haleakala and Mauna Loa. The ATLAS sensor is a single thermoelectrically-cooled STA1600 detector with 1.86 arcsecond per pixel platescale ($10.56k\times 10.56k$ pixels) giving a 29.2 square degree field of view. The two units work in tandem to survey the entire visible sky from $-40^\circ < \delta < 80^\circ$ with a cadence of two to four days, depending on weather. The ATLAS unit on Haleakala has been working in scientific survey mode since April 2016 and was joined by the Mauna Loa unit in March 2017.

ATLAS observes in two wide-band filters, called “cyan” or “ c ”, which roughly covers the SDSS/Pan-STARRS g and r filters, and “orange” or “ o ”, which roughly covers the SDSS/Pan-STARRS r and i . The observing cadence for identifying moving asteroids is typically to observe

each footprint 4-5 times (30 s exposures, slightly dithered) within about an hour of the first observation of each field. All data immediately go through an automatic data processing pipeline. This produces de-trended, sky-flattened images which are astrometrically corrected to the Gaia stellar reference frame and photometrically corrected using Pan-STARRS1 reference stars¹⁶. Difference images are produced using a static-sky template and source extraction is carried out on both the target and difference images using DOPHOT on the target frames³⁹ and a custom written package for PSF-fitting photometry, which we call TPHOT (on the difference frames). Sources found on the difference images are then cataloged in a MySQL database and merged into astrophysical objects if there are at least three detections from the five (or more) images. These objects are subject to a set of quality filters, a machine-learning algorithm and human scanning^{16, 40}.

Our database did not contain any astrophysical object at the position of AT2017gfo between MJD 57380.64463 and 57966.26370. The position was observed 414 times and on each of these we forced flux measurements at the astrometric position of the transient on the difference image. We measured 5σ flux limits and any epochs with greater than 5σ detections. The 5σ flux limits were in the range $o > 18.6 \pm 0.5$ (AB mag, median and standard deviation) and $c > 19.3 \pm 0.4$ (see Extended Data Figure). We found 44 images which formally had flux detections greater than 5σ , but on visual inspection we rule out these being real flux variability at the transient position. They all appear to be residuals from the host galaxy subtraction. With ATLAS, we rule out any variability down to 18.6 to 19.3 (filter dependent) during a period 601 to 16 days before discovery of AT2017gfo.

We can estimate an approximate upper limit to the rates of these kilonovae, without a GW

trigger from the ATLAS survey. Extended Data Figure 2 implies that we would be sensitive to objects like AT2017gfo to 60 Mpc. ATLAS typically surveys 5000 sq deg per night, 4-5 times, which provides a sampled volume of 10^{-4} Gpc^3 within 60 Mpc. If we assume that a kilonova lightcurve is visible for 4 days and we have observations every 2 - 4 days, and observe 60% of clear time then the control time is 0.9 yr. We have no candidates, therefore the simple Poisson probabilities of obtaining a null result are 50%, 16% and 5% when the expected values are 0.7, 1.8 and $3.0 \times 10^4 \text{ Gpc}^{-3} \text{ yr}^{-1}$. Therefore the 95% confidence upper limit to the rate of kilonovae is $< 3.0 \times 10^4 \text{ Gpc}^{-3} \text{ yr}^{-1}$. This simple approach is in broad agreement with the upper limit from the Dark Energy Survey⁴¹ and the LIGO Scientific collaboration for NS-NS mergers⁴² and a more sophisticated calculation is warranted for the ATLAS data.

The Pan-STARRS1 system and observational data The Pan-STARRS1 system⁴³ comprises a 1.8 m telescope with a 1.4 Gigapixel camera (called GPC1) mounted at the Cassegrain $f/4.4$ focus. This wide-field system is located on the summit of Haleakala on the Hawaiian island of Maui. The GPC1 is composed of sixty Orthogonal Transfer Array devices (OTAs), each of which has a detector area of 48460 x 48680. The pixels are 10 microns in size (0.26 arcsec) giving a focal plane of 418.88 mm in diameter or 3.0 degrees. This corresponds to field-of-view area of 7.06 square degrees, and an active region of about 5 square degrees. The filter system (which we denote *grizy_{P1}*) is similar to the SDSS⁴⁴ and is described in detail in two papers^{43,45}. Images from Pan-STARRS1 are processed immediately with the Image Processing Pipeline⁴⁶. The existence of the Pan-STARRS1 3π Survey data⁴³ provides a ready made template image of the whole sky north of $\delta = -30^\circ$, and we furthermore have proprietary *i_{P1}* data in a band between $-40^\circ < \delta < -30^\circ$,

giving a reference sky in the i_{P1} band down to this lower declination limit. Images in $i_{P1}z_{P1}y_{P1}$ were taken on 7 nights, at high airmass due to the position of AT2017gfo.

A series of dithered exposures were taken in the three filters during the first available night (starting 2017 Aug 18 05:33:01 UT), and we placed the target on a clean detector cell. We repeated the $i_{P1}z_{P1}y_{P1}$ for two subsequent nights until the object became too low in twilight and we switched to z_{P1} and y_{P1} and then only y_{P1} . Frames were astrometrically and photometrically calibrated with standard Image Processing Pipeline steps^{46, 47, 48}. The Pan-STARRS1 3π reference sky images were subtracted from these frames⁴⁹ and photometry carried out on the resulting difference image⁴⁷.

ePESSTO and Xshooter observational data EFOSC2 consists of a combined 2048×2048 pixel CCD imaging camera and low-dispersion spectrograph, mounted at the Nasmyth focus of the 3.58 m New Technology Telescope (NTT) at La Silla, Chile. The SOFI instrument has a 1024×1024 pixel near infra-red array for long-slit spectroscopy and imaging, and is also mounted at the NTT on the other Nasmyth focus. All EFOSC2 spectra were taken at the parallactic angle using the configurations listed in Table 1, and reduced using the PESSTO pipeline¹⁵. Spectroscopic frames were trimmed, overscan and bias subtracted, and divided by a normalised flat field. In the case of the Gr#16 spectra, a flat field was obtained immediately after each spectrum to enable fringing in the red to be corrected. Spectra were wavelength calibrated using arc lamps, and the wavelength solution checked against strong sky emission lines. Cosmic rays were masked in the two-dimensional spectra using the LACosmic algorithm⁵⁰, before one-dimensional spectra were optimally extracted from each frame. Flux calibration of the spectra was done using an average sensitivity curve de-

rived from observations of several spectrophotometric standard stars during each night, while the telluric features visible in the red were corrected using a synthetic model of the absorption.

The Xshooter instrument on the ESO Very Large Telescope was used for two epochs of spectra. The observational setup and spectral reductions were similar to those previously employed in and detailed in several publications^{51, 52}, with the custom-built T. Krühler reduction pipeline used for the reduction and flux calibration and *molecfit* package used for telluric correction. All spectra were scaled to contemporaneous photometric flux calibrations. Images with the NACO and VISIR instruments on the ESO Very Large Telescope were taken in the L -band (NACO) and N -band (VISIR) in the mid-infrared. These were kindly made public by ESO to all collaborating groups working with the LIGO-Virgo follow-up programmes and are publicly available through the ESO archive. We found no detection of the transient in either instrument. The host galaxy NGC4993 was faint, but visible in the L -band NACO images. With only one standard star, at a vastly different airmass from the target we could not reliably determine an upper limit. Similarly, no flux was visible in the VISIR N -band data.

The EFOSC2 and SOFI images were reduced using the PESSTO pipeline. All EFOSC2 images were overscan and bias subtracted, and divided by a flat-field frame created from images of the twilight sky. Individual images taken at each epoch were then aligned and stacked. The SOFI images were cross-talk and flat-field corrected, sky subtracted, aligned, and merged. The transient had faded below the detection limit in the $g'r'i'z'$ GROND images obtained on 2017 August 26.97 UT, and the U EFOSC2 image observed on 2017 August 21.05 UT. The VISTA Hemisphere survey JK_s images observed on 2014 April 10 were used as references for the SOFI JK_s images. No

VISTA archive images were available in H -band, therefore we used the GROND H -band on 2017 Aug 29.99 UT as the reference. Template image subtraction to remove the contribution from the host galaxy was carried out based on the ISIS2.2 package⁵³, and the subtractions were of good quality. Point-spread function (PSF) fitting photometry was carried out on each stacked and template-subtracted image. An empirical model of the PSF was made for each image from sources in the field, and fitted to the transient to determine its instrumental magnitude. In the case where the transient was not detected, artificial star tests were used to set a limiting magnitude. The photometric zeropoint for each image was determined through aperture photometry of Pan-STARRS1 or 2MASS sources in the field of the EFOSC2 and SOFI images, respectively, and used to calibrate the instrumental magnitudes onto a standard system. Three further epochs were taken with the Boyden 1.52-m telescope in South Africa, giving extra time resolution coverage over the first 72 hrs. The Boyden 1.52-m telescope, is a 1.52 m Cassegrain reflector combined with an Apogee 1152 \times 770 pixel CCD imaging camera, providing a field of view of 3.7 arcmin \times 2.5 arcmin. Observations were carried out during twilight and the early hours of the night at low altitude using 30 sec exposures. Observations were reduced and analysed using a custom pipeline for this telescope. All photometric observations were taken using a clear filter and then converted to SDSS r using four Pan-STARRS1 reference stars.

GROND system and observational data Observations with GROND⁵⁴ at the 2.2 m Max-Planck telescope at La Silla ESO started on 2017 Aug 18 23:15 UT⁵⁵. Simultaneous imaging in $g'r'i'z'JHK_s$ continued daily, weather allowing until 2017 Sept 4 (see Tables 2 and 3). GROND data were reduced in the standard manner using pyraf/IRAF⁵⁶. PSF photometry of field stars was calibrated

against catalogued magnitudes from Pan-STARRS1^{43, 48} for $g'r'i'z'$ images and 2MASS for JHK_s images. The images were template subtracted using the ISIS2.2 package⁵³. GROND $g'r'i'z'$ images from 2017 Aug 26.97 UT and JHK_s images from 2017 Aug 29.99 UT were used as reference images. These were the best quality images we had with no detection of the source. The photometry results in typical absolute accuracies of ± 0.03 mag in $g'r'i'z'$ and ± 0.05 mag in JHK_s .

Spectral and lightcurve comparisons A comparison of our spectra with a sample of SNe is shown in Fig. 3. Both the spectral shape and features present differ significantly, with AT2017gfo showing a significantly redder SED than those of either Type Ia or Type II-P SNe within a few days of explosion. The spectra of AT2017gfo also lack the typical absorption features of intermediate-mass elements that are normally seen in early-time SN spectra. Fig. 3 also shows a comparison with optical spectra from a sample of some of the faintest and fastest evolving Type I SN discovered to date.

PESSTO has spectroscopically classified 1160 transients, and monitored 264, and none are similar to AT2017gfo. Volume-limited samples of supernovae (having samples of around 100-200 SNe within 30-60 Mpc) have never uncovered a similar transient^{57, 58}. In the ATLAS survey, during the period up to Aug 2017, we have found 75 transients (all supernovae) in galaxies within 60 Mpc and no objects like AT2017gfo. This implies that objects like AT2017gfo have a rate of around 1% or less of the local supernova rate, justifying our probability calculation in the main text.

Bolometric light curve calculation Firstly, the broad-band magnitudes in the available bands (U , g , r , i , z , y , J , H , K_s) were converted into fluxes at the effective filter wavelengths, and then

corrected for the adopted extinctions (see Methods - Distance and reddening). For completeness at early phases, we ensured consistency with the values for ultra-violet flux reported from the Swift public data in the bands *uvw2*, *uvm2*, *uvw1*, and *U*^{59, 60}. An SED was then computed over the wavelengths covered. Fluxes were converted to luminosities using the distance previously adopted. We determined the points on the bolometric light curve at epochs when *K*-band or ultra-violet observations were available. Magnitudes from the missing bands were generally estimated by interpolating the light curves using low-order polynomials ($n \leq 2$) between the nearest points in time. We also checked that the interpolated/extrapolated magnitudes were consistent with the available limits. Finally, we fitted the available SED with a black-body function and integrated the flux from 1000 Å to 25000 Å. This provides a reasonable approximation to the full bolometric light curve⁶¹ but we caution that flux beyond 25000Å may contribute. It is not clear that the spectral energy distribution at this phase is physically well represented by a black body, and therefore we chose not to integrate fully under such a spectrum. Therefore the bolometric flux that we estimate at 8 days and beyond could be higher. For reference we report the temperature and radius evolution, together with uncertainties, from the SED fitting in Table 4, although we again note that a black body assumption may not be valid at later times.

Light curve modelling - parameter range estimation We compare the light curve data with the models by Arnett and Metzger using a Bayesian framework⁶². The likelihood in our case is defined as $\mathcal{L} = e^{-\chi^2/2}$. The time of the kilonova (used on both models) is defined to be that of the gravitational-wave trigger time. For both the Metzger and Arnett models considered in this analysis, we choose a log uniform prior of $-5 \leq \log_{10}(M_{\text{ej}}) \leq 0$ for the ejecta mass, a uniform

prior of $0 \leq v_{\text{ej}} \leq 0.3 c$ for the ejecta velocity, and a uniform prior of $-1 \leq \log_{10}(\kappa) \leq 2 \text{ cm}^2 \text{ g}^{-1}$ for the opacity. Specifically for the Metzger model, we chose a uniform prior of $0 \leq \alpha \leq 10$ for the slope of the ejecta velocity distribution. The power-law slope for radioactive powering given in the Arnett model is given a prior of $-5 \leq \beta \leq 5$.

We sample this given posterior using a nested sampling approach using the MULTINEST implementation⁶³ through a PYTHON wrapper⁶⁴. Figure 4 shows the posterior of the Arnett model. Figure 5 shows the posterior of the Metzger model.

Systematic error for mass is dominated by uncertainty in the heating rate per mass of the ejecta. This consists of the product of intrinsic decay power, and thermalization efficiency. For the intrinsic decay power, we find values of $(1 - 3) \times 10^{10} \text{ erg g}^{-1} \text{ s}^{-1}$ in the literature^{2, 24, 25, 19}, $1.9 \times 10^{10} \text{ erg g}^{-1} \text{ s}^{-1}$ is our default value. There are only small uncertainties associated with nuclear mass models during the first few days, but this grows to a factor of ~ 2 -3 at later times¹⁹.

Due to the dominance of the post-diffusion tail in the fits, the mass scales roughly inversely with the powering level. Thus, if this is a factor of two higher than assumed our mass range declines by a factor of 2. However, the vast majority of decay models are close to our value, so we favour the $\sim 0.04 M_{\odot}$ solutions over the $\sim 0.02 M_{\odot}$ ones. We note also that even the high-opacity models fitting the later data points have $M \gtrsim 0.02 M_{\odot}$, so this should be a robust lower limit to the ejecta mass.

TARDIS Modelling details For the temperature implied by the black-body like SED, Fe would be expected to be primarily in its neutral or singly-ionized state: in either case, detectable features

would be expected. In particular, the lack of evidence for Fe II features (e.g. the Fe II $\lambda 5064$ multiplet) in the blue part of our spectrum places a strong limit on the presence of this ion (simple TARDIS modelling suggests $< 10^{-3} M_{\odot}$ of Fe II can be present in the spectral forming region). This lack of Fe partly argues against ejecta compositions dominated by Fe-peak elements. Equivalent constraints on Ni, however, are weaker.

As noted in the main text, the combination of limited atomic data and simplistic modelling means that we cannot derive reliable elemental masses from the analysis carried out so far. However, we note that our model for the +1.4 d spectrum invokes ion masses of only $\sim 10^{-9} M_{\odot}$ and a few times $10^{-3} M_{\odot}$ for Cs I and Te I, respectively, at ejecta velocities above the adopted photosphere (i.e. $v > 0.2 c$). In both cases, these are only lower limits on elemental masses, since the ions in question are expected to be sub-dominant at the conditions present in the ejecta (this is a particularly important consideration for Cs I, owing to its low ionization potential of only 3.9 eV). Nevertheless, these mass limits are consistent with the ejecta masses suggested in our light curve model.

Kilonova simulations Kilonova simulations predict two distinct ejecta components: dynamic ejecta and disk winds. The dynamic ejecta is expelled directly in the merger. Starting from neutron star material with $Y_e \sim 0.03$, it experiences some moderated de-neutronization by positron captures, but likely ends with $Y_e \lesssim 0.2^2$. Such composition is predicted to produce all heavy r-process elements, including lanthanides and actinides. It is thus expected to lead to a high-opacity red component peaking on time scales of days/weeks. The disk wind has two components, a radiation driven wind and a dynamic torus ejection. These are exposed to neutrino irradiation, which can

produce a larger variation in Y_e . This component can thus be largely lanthanide and actinide free, and have low opacity, in particular for $0.2 < Y_e < 0.4$. Dynamic and wind ejecta have similar heating rates². Thus, their contribution to the bolometric light curve is largely proportional to their masses. The compilation by Wu et al.⁶⁵ shows that current simulations predict similar masses of the two components, but uncertainty of a factor few for their mass ratio.

The data suggests that we have detected the lower-opacity disk wind component, and that this has a Y_e in the range giving low opacity (giving constraints on the poorly understood Y_e setting processes). Whether a dynamic component is present as well is harder to ascertain. The whole light curve is reasonably well fit by a single disk wind component. Our models are too simplistic to warrant exploration of two-component scenarios. Assuming we have detected a disk wind of several times $0.01 M_\odot$, it is not easy to make this component drop away enough at late times to leave much flux for a dynamic ejecta component. Perhaps the opacity in the dynamic ejecta is as high ($\kappa \gtrsim 100 \text{ cm}^2 \text{ g}^{-1}$) as speculated^{3,66}, and it then remains too dim to be seen compared to the wind for at least the first 20 days. Alternatively, this kilonova has simply $M_{wind} \gg M_{ejecta}$. The only circumstance which could substantially change these conclusions is if the first 2–3 data points are caused by a GRB afterglow. Then, a dynamic component with $\kappa \gtrsim 10 \text{ cm}^2 \text{ g}^{-1}$, can reasonably well fit the later data points. However, as we discuss in the main paper we find several arguments against this scenario, such as the chromatic light curve evolution and the absence of a strong X-ray afterglow, and assess that the early light is caused by a blue kilonova.

Data Availability Statement The reduced, calibrated spectral data presented in this paper are openly

available on the Weizmann Interactive Supernova data REPOSITORY (<https://wiserep.weizmann.ac.il>) and at the ePESSTO project website <http://www.pessto.org>. The raw data from the VLT, NTT and GROND (for spectra and imaging) are available from the ESO Science Archive facility <http://archive.eso.org>. The raw pixel data from Pan-STARRS1 and the 1.5m Boyden telescope are available from the authors on request.

Code Availability The lightcurve fitting code described here is publicly available at the following website: <https://star.pst.qub.ac.uk/wiki/doku.php/users/ajerkstrand/start>. A code to produce the posteriors in this paper is available at: <https://github.com/mcoughlin/gwemlightcurves>. TARDIS is an open-source Monte Carlo radiative-transfer spectral synthesis code for 1D models of supernova ejecta and is publicly available here <https://tardis.readthedocs.io/en/latest/>. Standard software within the IRAF environment was used to carry out the spectral, and imaging reductions and photometry.

Acknowledgements This work is based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere, Chile as part of ePESSTO, (the extended Public ESO Spectroscopic Survey for Transient Objects Survey) ESO program 199.D-0143 and 099.D-0376. We thank ESO staff for their excellent support at La Silla and Paranal and for making the NACO and VISIR data public to LIGO-Virgo collaborating scientists. We thank Jacob Ward for permitting a time switch on the NTT. PS1 and ATLAS are supported by NASA Grants NNX08AR22G, NNX12AR65G, NNX14AM74G and NNX12AR55G. Part of the funding for GROND was generously granted from the Leibniz-Prize to Prof. G. Hasinger (DFG grant HA 1850/28-1). Pan-STARRS1 and ATLAS are supported by NASA Grants NNX08AR22G, NNX12AR65G, NNX14AM74G and NNX12AR55G issued through the SSO Near Earth Object Observations Program. We acknowledge the excellent help in obtaining GROND data from Angela Hempel, Markus Rabus and Régis Lachaume on La Silla. The Pan-STARRS1 Surveys (PS1) were made possible by the IfA, University of Hawaii, the Pan-STARRS Project Office, the Max-Planck Soci-

ety, MPA Heidelberg and MPE Garching, Johns Hopkins University, Durham University, University of Edinburgh, Queen’s University Belfast, Harvard-Smithsonian Center for Astrophysics, Las Cumbres Observatory Global Telescope Network Incorporated, National Central University of Taiwan, Space Telescope Science Institute, National Science Foundation under Grant No. AST-1238877, University of Maryland, and Eotvos Lorand University (ELTE) and the Los Alamos National Laboratory. Extended Data

Extended Data Figure 1 | Light curves of AT2017gfo **a)** Observed AB light curves of AT2017gfo, vertically shifted for clarity. The 1σ uncertainties are typically smaller than the symbols. **b)** Comparison of the absolute r -band light curve of AT2017gfo with those of a selection of faint and fast SNe 2005E⁶⁷, 2005ek⁶⁸, 2010X⁶⁹, 2012hn⁷⁰, and OGLE-2013-SN-079⁷¹ (OGLE13-079). The comparison event phases are with respect to maximum light, while for AT2017gfo with respect to the LIGO trigger.

Extended Data Figure 2 | ATLAS limits at the position of AT2017gfo: 5σ upper limits (from forced photometry) at the position of AT2017gfo up to 601 days before discovery in the ATLAS images. The *cyan* and *orange* filter limits are plotted as those colours. These limits are measured on the difference images, which are the individual 30 sec frames after having the ATLAS reference sky subtracted off. The points plotted represent (typically) 5 images per night, and are the median limits of those five 30 sec frames. The two horizontal lines indicate the AB *orange* mag of AT2017gfo at 0.7 and 2.4 days after discovery, illustrating that ATLAS has sensitivity to make discoveries within 1–2 days of NS-NS merger at this distance. The last non-detection is 16 days before discovery of AT2017gfo.

Extended Data Figure 3 | Spectral comparisons **a)** Comparison of our Xshooter spectra of AT2017gfo with early-time (4 - 5 days post explosion) optical and near infra-red spectra of Type Ia SN 2011fe⁷² and Type II-Plateau SN 1999em⁷³. The spectra have been scaled for comparison purposes. **b)** Comparison of our earliest spectrum of AT2017gfo (+1.4 days after explosion) with a sample of Type I events, which share some common properties with AT2017gfo such as faint absolute magnitudes and/or fast evolution and/or explosion environments without obvious star formation. **c)** Comparison of the +4.4 day spectrum of AT2017gfo with our sample of faint and fast-evolving events at later phases.

Extended Data Figure 4 | Posterior probability plots of our model light curve fits. This is the Arnett formalism which includes a power law term for radioactive powering. We show the 68% quantile in all plots and 95% and 99.7% levels in the 2D histograms. We quote the maximum posterior fit value and the 68% quantile range as uncertainty.

Extended Data Figure 5 | Posterior probability plots of our model light curve fits for the parameterised Metzger model¹⁹ as described in the main manuscript. As in Fig. 4, we show the 68% quantile in all plots and 95% and 99.7% levels in the 2D histograms. We quote the maximum posterior fit value and the 68% quantile range as uncertainty.

Extended Data Table 1 | **Log of spectroscopic observations.** The phase is with respect to the LIGO-Virgo detection of 57982.528524.

Extended Data Table 2 | Optical photometric measurements. The UT and MJD are at the start of the exposure. The phase is with respect to the LIGO-Virgo detection of 57982.528524. All magnitudes are in the AB system. The GROND epoch on the 2017-08-26 was used as the reference template for image subtraction for all GROND epochs up to this date. All limits are 3σ .

Extended Data Table 3 | Near infra-red photometric measurements. The UT and MJD are at the start of the exposure. The phase is with respect to the LIGO-Virgo detection of 57982.528524. All magnitudes are in the AB system. The GROND epoch on the 2017-08-29 was used as the reference template for image subtraction for all GROND epochs up to this date. All limits are 3σ .

Extended Data Table 4 | Bolometric light curve, temperature and radius evolution. These values were calculated as described in the Methods section, L_{bol} is in erg s^{-1} . The two points at 0.642 and 1.042 days were estimated from the Swift data^{59, 60}. The phase is with respect to the LIGO-Virgo detection of 57982.528524.
