(Dated: February 2, 2018)

We realise bistability in the spin of polariton condensates under non-resonant optical excitation and in the absence of biasing external fields. Numerical modelling of the system using the Ginzburg-Landau equation with an internal Josephson coupling between the two spin components of the condensate qualitatively describes the experimental observations. We demonstrate that polariton spin bistability strongly depends on the condensate’s overlap with the exciton reservoir by tuning the excitation geometry and sample temperature. We obtain non-collapsing bistability hysteresis loops for a record range of sweep times, [10µs, 1s], offering a promising route to spin switches and spin memory elements.

Optical bistability is the phenomenon of an optical system supporting two or more stable states for a given range of driving conditions [1, 2]. A bistable behavior demonstrates an internal memory of the system, which could potentially be harnessed to form optical transistors and memory elements. It has been observed in systems such as cold atoms [3], lasers [4], self-electro-optic effect devices [5] and Fabry-Pérot cavities containing nonlinear materials [6, 7]. Optical bistability in microcavity polaritons, the bosonic quasi-particles formed by the strong coupling of cavity photons and excitons, was previously demonstrated for resonant/quasi-resonant optical excitation [8–13], electrical biasing [14, 15] and non-resonant electrical injection [16]. In resonantly pumped microcavity polaritons, bistability was described by a Kerr-like nonlinearity resulting from polariton-polariton interactions [9] and by employing an analogy with optical parametric oscillators [10]. Under electrical injection, bistability was observed in the photoluminescence intensity, in the presence of an external magnetic field, and was attributed to the electrostatic screening of the injected charge carriers forming a positive feedback for the backward sweep of the driving current [16].

Bistability has also been realised in the spinor of a polariton state utilising polaritons’ well defined spin and its one-to-one correspondence with the circular polarization of emitted light. Optical control of polariton spin was employed in the realisation of spin-bistability and multi-stability, using quasi-resonant optical excitation of a cylindrical mesa [8] by rotating the polarization of the optical pump. Recently, spin-bistability was also shown under non-resonant optical excitation in a mesa structured microcavity using a biasing electrical field to induce an energy splitting between two linear polarization modes, while keeping the optical excitation constant [14]. Under non-resonant pumping and in the absence of external fields, the preferable route for the operation of all-optical memory elements in polariton circuits, both polariton bistability and spin-bistability remain elusive, despite theoretical predictions [17].

For the observation of polariton bistability or spin-bistability, it is essential that the population fluctuations of polaritons or the relative spin populations, remain sufficiently small so as not to bridge the two stable solutions of the system that would lead to a collapse of the hysteresis loop. Polaritons are an inherently open-dissipative, non-equilibrium system that requires continuous pumping to reach steady-state due to finite cavity lifetime. In the absence of external electric or magnetic fields, polariton bistability and spin-bistability has been observed only under resonant excitation; the fundamental difference between resonant and non-resonant optical pumping is the presence, in the latter case, of a hot-exciton reservoir, and the concomitant exciton-polariton interactions. Exciton-polariton pair scattering events contribute to the decoherence of polaritons [18, 19], however, the observed bistabilities in polariton systems occur at time scales that can exceed the coherence time of a polariton condensate by a factor of $10^3$, suggesting that it is not the exciton induced decoherence that precludes the observation of bistability under non-resonant pumping. Another source of instability that prevents bistable behavior under non-resonant pumping is the density fluctuations induced by the hot-exciton reservoir. Similarly, exciton-polariton interactions are a strong source of spin mixing [20] that, in the presence of an initial spin imbalance, result in changes of the relative spin populations that prevent the realisation of spinor polariton bistability.
In this letter, we realize spin-bistability under non-resonant optical pumping, in the absence of external fields, by spatially separating the spin-bistable polariton state from the hot-exciton reservoir, thus strongly suppressing spin depolarisation in the system. The spin-bistability is evidenced on the spinor of a polariton condensate, trapped at the centre of an annular excitation beam, in the form of a hysteresis loop in the degree of circular polarization versus the optical excitation power. We attribute the spin-bistability to an interplay of polariton nonlinearities with the internal Josephson coupling of the two spin components. Figure 1 depicts a schematic of the system; the red ring on the surface of the microcavity, shows the pumping intensity profile. The rainbow colored Gaussian, in the centre of the ring, shows the measured polariton density of the ground state, $\psi_{00}$. The black mesh annular barrier represents the repulsive potential due to the optically injected hot-exciton reservoir. The red and blue spheres in the centre of the ring represent the two spin components of the polariton condensate that are coupled via an internal Josephson coupling, $J$.

The microcavity we use in this study is a $5\lambda/2$ cavity with GaAs quantum wells (QWs), as in [21], held at $\sim$6 K using a continuous flow cold finger cryostat. We excite the sample with a linearly polarized, continuous wave (CW), monomode laser, tuned to the first reflectivity minimum at 754 nm. A spatial light modulator (SLM) imprints a phase profile, and the desired annular pump geometry is focused on the sample surface by a 0.4 numerical aperture (NA) microscope objective lens. The intensity of the laser is modulated into triangular pulses using an acousto-optical modulator (AOM) that is driven by a triangular voltage pulse train. A polarization analyser is used to record the two cross-circular components.
of the photoluminescence intensity. The top schematic of Fig. 2 shows the setup and the triangular laser pulse train used to excite the sample. The use of a high NA excitation lens introduces a $\sim10\%$ ellipticity to the pump beam [22], which creates a small spin imbalance in the injected carriers. Since the electron spin relaxation time in GaAs QWs is longer than the carrier relaxation time to the exciton reservoir, the initial electron spin imbalance is reflected in the spin imbalance of the exciton reservoir that in turn leads to a spin polarized polariton condensate [23]; by separating the polariton condensate from the exciton reservoir here, we observe 93\% degree of circular polarization (DCP).

Figure 2(a) shows a typical hysteresis loop in the DCP, represented by the $S_Z$ component of the Stokes polarization vector versus the pump power normalized to the condensation threshold at a detuning of $-7.6meV$. With increasing pump power, shown with a red dashed line in Fig. 2(a), we observe a spin reversal as it was previously observed in time integrated measurements [23]. The spin reversal was attributed to the transition into a desynchronization regime in Ref.[23] through the complex spin-dependent Ginsburg-Landau equations (GLE) with an internal Josephson coupling term between the two spinor components. With decreasing pump power (blue solid line), a backwards spin reversal is observed at a lower pumping power compared to the power for the spin reversal observed in the forward direction. The signature of spin bistability is qualitatively reproduced numerically with the same theoretical model of Ref.[23] as shown in Fig. 2(b); see Appendix A of the Supplemental Material.

To gain an understanding of the nature of polariton spin bistability, in the following we draw analogues with the driven damped pendulum. We non-dimensionalize the complex spin-dependent Ginsburg-Landau equation and the rate equation describing the density in the exciton-reservoir and reduce them to the equation of a driven-damped pendulum:

$$\dot{\Theta} + \beta(p) \dot{\Theta} = -I_{\text{bias}}(p) - I_{\text{cr}}(p) \sin \Theta,$$

where $\Theta$ is the phase difference between two spin components, $\beta$ is a damping coefficient (positive above threshold) that increases with pumping power approaching a value of 1/2, $I_{\text{bias}}$ is equivalent to the driving torque of a pendulum and $I_{\text{cr}}$ is equivalent to the maximum gravitational torque. A description of the process of non-dimensionalization and reduction is presented in Appendix A of the Supplemental Material.

A driven damped pendulum supports two types of solution [24]: if the torques’ ratio $I = |I_{\text{bias}}|/|I_{\text{cr}}| \leq 1$, then the pendulum’s trajectory is attracted to a fixed point (stationary solutions regime), where the angular displacement is constant ($\dot{\Theta} = 0$) for a fixed driving torque. Alternatively, if $I > 1$, then $\dot{\Theta} \neq 0$, in which case the pendulum continues to overturn even under a fixed driving torque (limit cycle solutions regime). In this scheme, bistability occurs in the backward ramp of the driving torque due to its inertia, where the backward ramp corresponds to decreasing pump power.

Here, the stationary solutions regime results in the phases of the two spin states evolving synchronously with a constant phase difference; top branch of the bistability in Fig. 2(a,b). The limit cycle solutions regime, $\dot{\Theta} \neq 0$, results in the desynchronised evolution of the spin states’ phases. With decreasing pump power, the role of the “inertia” increases due to the decrease of the damping rate $\beta$, which allows for the limit cycle solutions regime to persist for pump powers lower than those on the forward ramp, leading to the observed hysteresis. A schematic comparison between bistability in the driven damped pendulum and the spinor polariton condensate is presented in Appendix B of the Supplemental Material.

In the following, we investigate the dependence of the observed bistability on the overlap, $\Omega$, between the condensate and the hot-exciton reservoir. At low temperatures, the pump induced exciton reservoir is co-localised with the pump beam due to the small (sub-micron) exciton diffusion length, which allows us to control $\Omega$ by changing the diameter of the annular pump profile. For diameters ranging 11.8$\mu$m to 17.9$\mu$m polariton condensation occurs in a Gaussian-shaped ground state, $\psi_{00}$. Figure 3(a) shows the dependence of the hysteresis area on the diameter of the annular pump at a detuning of $-7.6meV$ (black diamonds). With increasing pump diameter from 11.8$\mu$m to 17.9$\mu$m the hysteresis area increases monotonically. The (red) dotted line in Fig.3(a) shows the calculated $\Omega$ assuming a Gaussian-shaped condensate and an annular pump profile with a Gaussian cross section, where the width of the condensate and the annular profile are approximated from the measured photoluminescence under different annular pump diameters. When the diameter of the annular pump exceeds 18$\mu$m, the trapping potential allows for the coexistence of higher order Hermite-Gaussian-shaped, $\psi_{01}$, condensates with the $\psi_{00}$ condensate [25], this leads to the collapse of the hysteresis loop. The hysteresis loops vs the diameter of the annular pump are presented in Appendix C of the Supplemental Material. The deleterious effect of exciton-polariton interactions on bistability is further corroborated by changing the exciton fraction of polaritons. The solid black circle in Fig.3(a) shows the hysteresis area obtained for an annular pump diameter of 13.1$\mu$m at a detuning of $-11.2meV$.

Figure 3(b) shows the hysteresis area vs temperature ranging from 4 K to 40 K, where strong coupling is sustained [26]. With increasing temperature the exciton linewidth, the exciton reservoir lifetime, the exciton diffusion length and the exciton-photon detuning are increasing. All of these effects contribute in the suppression of the hysteresis area. We note that the observed hysteresis loops under all previous excitation and detuning
We observe that the dependence of the hysteresis area as a function of the sweep time exhibits a double power-law decay. The mean-field approach of the spin-dependent Ginzburg-Landau model implemented here to explain the observed bistability cannot reproduce the dependence of the hysteresis area on the sweep time. Recently, a double power-law decay vs the sweep time was attributed to quantum fluctuations [29]. An evolution from a double to a single power-law decay was experimentally observed with increasing the average photon number and was ascribed to a dissipative phase transition between the quantum regime and the thermodynamic limit [13]. The dissipative phase transition was shown to depend strongly on the laser-cavity detuning; here spinor bistability is observed under non-resonant optical pumping.

In summary, we demonstrate optical bistability in spinor polariton condensates under non-resonant optical excitation in the absence of external biasing fields. The hysteresis loop can be qualitatively modelled through the complex spin-dependent Ginzburg-Landau equations with an internal Josephson coupling term between the two spinor components. We unravel the detrimental role of a hot-exciton reservoir on bistability by controlling the overlap of the pump induced exciton reservoir and the polariton condensate. The dependence of spin bistability on the condensate’s overlap with the exciton reservoir allows us to control the hysteresis area by tuning the excitation geometry. Most importantly, we obtain non-collapsing bistability hysteresis loops for a record range of sweep times, [10µs, 1s], offering a promising route to spin switches and spin memory elements.
