A Complex Panning Method for Near-field Imaging

Dylan Menzies and Filippo Maria Fazi

Abstract—Conventional amplitude panning can be used to produce images of distant objects. A panning method is presented here that can also produce image cues for the near-field region, by the control of Inter-aural Level Difference cues in the low frequency range below 700Hz. A single first order filter is required for each image. The approach has grown from an adaptive panning method that corrects for the dependence of image orientation on head orientation. A formulation is presented in a low frequency approximation. Cues are then calculated for various configurations using measured Head Related Transfer Functions. These results, and a listening test, confirm the ability of the method to control near-field cues, while also compensating for head rotation.

MATHEMATICAL SYMBOLS

\( k \) wavenumber
\( \omega \) angular frequency
\( Z_0 \) characteristic impedance of sound in air
\( P \) pressure of the incident free field at the head centre position
\( P_L, P_R \) resultant pressures at the ears
\( V \) velocity vector of the incident free field at the head centre position
\( V_R \) and \( V_\Delta \) real and imaginary components of \( V \)
\( r_L, r_R \) displacement vectors from the head centre to each ear (bold type for vectors).
\( \hat{r}_R, \hat{r}_L \) direction vectors to the stereo loudspeakers from the listener
\( r_I \) distance to image
\( \hat{r}_V \) Makita localisation vector (\( \hat{r}_V = -\hat{V} \))
\( \theta_{VN}, \theta_{IN}, \theta_{IV} \) azimuth change from direction indicated by 1st subscript to 2nd. \( V: r_V, N: \text{ nose}, I: \text{ image} \)
\( \theta_L \) \( 2\theta_L \) is the stereo loudspeaker separation from the listener
\( \theta_N \) directed angle from the mid point between stereo loudspeakers to the direction the listener is facing in
\( \theta_I \) directed angle from the mid point between stereo loudspeakers to the image
\( g_1, g_2 \) stereo panning gains
\( \hat{r}_1, \hat{r}_2 \) direction vectors to the stereo loudspeakers from the listener
\( h_{1L}, h_{1R} \) head related impulse responses from each loudspeaker (1,2) to each ear (L,R)

I. INTRODUCTION

In previous studies, the Inter-aural Time Difference (ITD) and Inter-aural Level Difference (ILD) localisation cues, were modelled for general low frequency sound fields. The model was then applied to the problem of panning reproduction, the creation of an image by the summation of coherent plane waves from multiple loudspeakers. If the head orientation is known, then the panning gains can be adjusted so that the resulting field produces the same localisation cues as a plane wave travelling from the target image direction. In this case the low frequency ILD is 0 dB. General stereo panning formula were found that include the listener’s head orientation. Calculation with measured Head Related Transfer Functions predicts that this panning process produces stable images, for a wide range of configurations, making significant improvements over conventional panning processes that do not consider the head orientation. Furthermore, low frequency images can be generated in any direction, including behind, at the sides and above or below. This is because accurate ITD cues naturally lead to accurate dynamic ITD cues, which provide unambiguous imaging in all directions. The method is referred to as Compensated Amplitude Panning (CAP). A real-time implementation for the method has been constructed, including real-time head tracking to sense the position and orientation of the listener’s head.

Brungart performed a comprehensive set of listening experiments in anechoic conditions on the localisation of sources within 1 m from the listener, which he calls the proximal region. One conclusion is that the main cue for source proximity is ILD in the frequency region below 750 Hz. The contribution from the ILD as a distance cue reduces with increasing frequency, and becomes insignificant above 3 KHz. It appears that for high frequencies ILD is too saturated at a high value to allow the auditory system to discriminate source range, whereas the ILD variation at low frequencies is useable. Furthermore, range perception by ILD also depends on knowledge of head orientation. It may be that at low frequencies the ITD cue provides a more reliable and accurate source for orientation, which further enhances the effectiveness of ILD range cues in the low frequency region.

Studies have investigated the degrading effect of room reflections on ILD range cues from the direct signal. These
show that a precedence effect occurs such that the effect of reflections is largely suppressed. This is supported by common experience in which near-field imaging is largely unaffected by nearby surface reflections.

In this work the CAP formula are extended, by matching the localisation cues to those of a nearby point source, rather than a plane wave. By simultaneously controlling ILD and ITD in the low frequency region, the aim is to produce stable images with controllable direction and range in the near-field, while retaining the existing ITD correction depending on head orientation.

The remaining content is as follows. In Section II, the low frequency approximation for binaural signals is reviewed. These are used in Section III to find expressions for the localisation cues, ITD and ILD, in terms of a general field description and the listener’s head orientation. In the previous work a relation was then found between a target image direction, the head orientation and the field description, by considering the cues for an incident plane wave travelling from the target image direction. Here this is extended by considering the cues for a near source positioned at the desired image location. The ILD for the near source varies with distance from the listener. In Section IV, extended stereo panning functions are derived, where the cue for a plane wave travelling from the target image position. In Section V, the method is extended by calculating the cues using a spherical head model and measured HRTFs, focusing on the ILD cue for different head rotations. The direction cue provided by the ITD is also assessed for accuracy, since this may be reduced when compared with the existing CAP method for panning of far images. A supporting listening test is reported in Section VI. The results are discussed further in Section VII.

II. SOUND FIELD REPRESENTATION

A source free sound field region can be expanded as a Taylor series about any point in the region. The first order approximation of the pressure \( P \) at a point \( x \), expanded about point \( x_0 \), can be given in the frequency domain in terms of pressure and pressure gradient \( \nabla P \) by

\[
P(x) \approx P(x_0) + \nabla P(x_0) \cdot (x - x_0)
\]

The approximation is good provided the wavelength is considerably larger than the distance \( |x - x_0| \), and higher order derivative terms are small compared with \( P(x_0) \), \( \nabla P(x_0) \), which is usually the case when a source is not close to \( x_0 \). This condition can be written \( kr << 1 \) where \( k = \frac{\omega}{c} \) is the wavenumber and \( r = x - x_0 \). Below around 700 Hz, a typical sound field region just large enough to enclose the human head satisfies these conditions.

The binaural signals are not equal to the pressures at the corresponding locations in the incident field, even at low frequency, due to the non-vanishing scattered field at the head surface. Using a spherical model for the head, with ears at antipodal locations, an analytical approximation can be found for the binaural signals. The ITD is found to have a low frequency limit value of \( \frac{3D}{2c} \cos \theta \), and constant ILD of 1 (or 0 in dB), where \( D \) is the ear separation, \( c \) is the speed of sound, and \( \theta \) is the angle separating the direction of the incident plane wave and the inter-aural axis. The free-field ITD is the ITD measured at the ear locations in the absence of the head, and is \( \frac{D}{c} \cos \theta \). The resultant pressure field on the sphere, radius \( r = D/2 \), is equal to the pressure of the incident free-field plane wave on the corresponding sphere at radius \( \frac{3}{2}r \). Since any field in a free-field region can be approximated arbitrarily well by a plane wave expansion, then for any incident field at low frequency, including near source fields, the resultant pressure at the surface of a rigid sphere of radius \( r \) can be approximated by the incident field, evaluated at radius \( \frac{3}{2}r \), provided it is homogenous up to this radius.

With the above considerations applied to a general first order field, the binaural signals at the right and left ears can be approximated as

\[
P_R \approx P + \bar{r}_R \cdot \nabla P
\]

\[
P_L \approx P + \bar{r}_L \cdot \nabla P
\]

where \( P \) and \( \nabla P \) are the pressure and gradient of the incident field at the central point between the ears, in the centre of the head, and is \( \bar{r}_R \cdot \bar{r}_L \cdot \nabla P \). For the remaining content, see the original document.
Fig. 2 illustrates the general case using the complex plane. Both $V_R$ and $V_3$ are non-zero, and in different directions. As the listener’s head rotates around any axis, $P_R$ and $P_L$ move around on opposite sides of an ellipse, shown with the dashed line. This is because $\hat{r}_R \cdot V_R = \hat{r}_R \cdot \hat{V}_R$ and $\hat{r}_R \cdot V_3 = \hat{r}_R \cdot \hat{V}_3$, where $\hat{V}_R$ and $\hat{V}_3$ are $V_R$ and $V_3$ projected in any plane to which the rotation axis is normal. $\hat{r}_R \cdot \hat{V}_R$ and $\hat{r}_R \cdot \hat{V}_3$ each vary as sinusoids of the angle $r_R$ with any reference direction in the plane, possibly with different amplitudes and phases, resulting in an ellipse.

Fig. 2: $P_R$ and $P_L$ in the complex plane for non zero and non-aligned $V_R$ and $V_3$

An omnidirectional point source is used to model a source in the near-field region of the listener. The velocity and pressure components are calculated as follows. The pressure field of a point source is

$$P = \frac{A}{r_S} e^{-jkr_S} \tag{8}$$

where $A$ is the complex amplitude of the source and $r_S$ is the distance from source. The gradient is

$$\nabla P = -P(\frac{1}{r_S} + jk)\hat{r}_S \tag{9}$$

where $\hat{r}_S$ is the unit vector in the direction from the source to the listener. Using (4),

$$V = \frac{P}{Z_0} (1 - \frac{j}{k r_S})\hat{r}_S \tag{10}$$

The complex velocity components are then

$$V_R = \frac{P}{Z_0} \hat{r}_S \tag{11}$$

$$V_3 = -\frac{P}{Z_0 r_L} \hat{r}_S \tag{12}$$

Note that $\hat{V}_R = -\hat{V}_3 = \hat{r}_S$, the direction from the source to the listener. If the source is distant then as noted earlier the linear approximation is valid provided $kr_L \ll 1$. However this is not sufficient if the source comes close. For example the approximation can fail completely when $r_S = r_R$ and improves as $r_S$ increases. When the source is on the inter-aural axis and in the limit of low frequency it is straight forward to show that the relative error of the linear approximation for $P$ is $- (r_R/r_S)^2$. This is $1/16$ when $r_S = 4 r_R$, ie when the source is approximately 30cm from the head centre. The final effect of the approximation on reproduced cues will be become clearer later when the complex panning method is evaluated for various $r_S$.

III. LOCALISATION CUES AND REPRODUCTION

The localisation cues can be calculated from the binaural signals that were approximated in the previous section. For a single frequency $\omega$, the ITD cue is equal to $\phi_{RL}/\omega$ (also called the Inter-aural Phase Delay (IPD) in this context), where $\phi_{RL} = \arg(P_R/P_L)$ is the inter-aural phase difference\(^{15}\), shown in Fig. 2. The ILD cue is given by $|P_R/P_L|$. Using the approximations (6,7) the ITD and ILD can be found from the pressure $P$ and velocity $V$.

Consider now the problem of finding, for any target point source, all possible fields that evoke the same perceived image as this target. This is equivalent to finding fields giving rise to the same ITD and ILD as the target, disregarding other localisation cues. A trivial solution is given by the point source field itself. Another solution is provided by matching pressure and velocity, since in the low frequency approximation the pressure and velocity determine the ITD and ILD. The Ambisonic reproduction method employs this principle\(^{16}\).

There remains the possibility of pressure and velocity solutions that give the correct ITD and ILD but do not match the target field pressure and velocity. To find these first observe that the ITD and ILD depend on, and determine, the shape (but not the size) of the triangle $\triangle 0P_L P_R$ in Fig. 2. So if two given fields have triangles with the same shape, then they produce the same image, according to the cues considered.

So, given a desired image, consider a target point source field that would produce this image, with velocity and pressure components $V_R$, $V_3$ and $P$, described by (11) and (12). Let $\hat{V}_R$, $\hat{V}_3$ and $P$ be the components of a general field with ITD and ILD that match those of the target field. The shape of the triangle shown in Fig. 2 is determined by two ratios, $\Re{P_R - P} / P$ and $\Im(P_R - P) / P$ (equally $P_L$ could be used). Evaluating these separately for the general field and the target point source field, by substituting for $V_R$, $V_3$ and $P$ in (6) and (7) gives,

$$\Im(P_R - P) / P = \begin{cases} k \Re{\hat{r}_R \cdot \hat{V}_R} / \Re{P} & \text{target field} \\ k Z_0 \Re{\hat{r}_R \cdot \hat{V}_R / \Re{P}} & \text{general field} \end{cases} \tag{13}$$

$$\Re(P_L - P) / P = \begin{cases} -k \Re{\hat{r}_R \cdot \hat{V}_L / r_L} & \text{target field} \\ -k Z_0 \Re{\hat{r}_R \cdot \hat{V}_3 / \Re{P}} & \text{general field} \end{cases} \tag{14}$$

Equating the two parts for each ratio gives two conditions for matching the cues,

$$\hat{r}_R \cdot (\Im(V) - \hat{r}_I) = 0 \tag{15}$$

$$\hat{r}_R \cdot (\Re(V) + \hat{r}_L / kr_I) = 0 \tag{16}$$

where $\hat{r}_I$ and $r_V$ are defined for convenience as follows: $\hat{r}_I$ is the direction from the listener to the image, which is opposite to the direction of the real part of the target velocity,

$$\hat{r}_I = -\hat{V}_R \tag{17}$$

$r_I = r$, the distance between the listener and the image. $r_V$ describes the general field, and coincides with the Makita Localisation Vector given by Gerzon\(^{16}\), and extended for complex values,

$$r_V = -\hat{V} Z_0 / \Re{P} \tag{18}$$
\( r_R \) has been replaced with the unit vector in the same direction, \( \hat{r}_R \). The size of the listener’s head represented by \( r_R \) is not needed for finding solutions for the general field.

It is apparent from (15) and (16) that, given an image location described by \( \hat{r}_I \) and \( r_I \), and a head orientation, which determines \( \hat{r}_R \), there is a continuous set of \( r_V \) and corresponding fields that produce the desired image. The vector diagram in Fig. 3 shows a projection from above the listener. Possible values of \( \Re(r_V) \) and \( \Im(r_V) \) lie on the two planes normal to the page and passing through the two straight dotted lines. The full set of consistent values for \( \hat{r}_I \) forms a circle around the inter-aural axis in the plane for \( \Re(r_V) \), commonly known as the cone of confusion. The effect of head orientation on image direction was discussed in detail previously.\(^1\)

\[ r_V = -Z_0 \frac{V}{P} = -Z_0 \frac{\sum V_i}{\sum P_i} = -\frac{\sum g_i \hat{V}_i}{\sum g_i} \]

This is in agreement with the original definition of Makita Localisation Vector in terms of panning gains.\(^1\) In this section, complex values are allowed for the gains and \( r_V \), in order to control ILD in addition to ITD. The term complex panning is used to distinguish from sound field reproduction methods, such as Ambisonics that may also use complex valued gains.

The near-field panning problem is to find panning gains \( \{g_i\} \) that produce a given image direction \( \hat{r}_I \) and range \( r_I \) for a given head direction \( \hat{r}_R \). A solution is first sought for two loudspeakers, since this is the most restrictive case. To simplify calculation the following additional constraint is imposed,

\[ g_1 + g_2 = 1 \] (20)

This does not restrict the solution search in practice since any unconstrained solution \((g_1, g_2)\), is a multiple of a constrained solution \((\hat{g}_1, \hat{g}_2) = (g_1, g_2)/(g_1 + g_2)\). (20) also normalises the pressure \( P \) at the listener to a constant value, so that the perceived low frequency volume can be controlled using an additional scaling factor applied to the gains.

The new constraint (20) allows (15) and (16) to be written in terms of separate sets of variables \((\Re(g_1), \Re(g_2))\) and \((\Im(g_1), \Im(g_2))\). Splitting the constraint into real and imaginary parts,

\[ \Re(g_1) + \Re(g_2) = 1 \]

\[ \Im(g_1) + \Im(g_2) = 0 \]

hence from (19),

\[ \Re(r_V) = \Re(g_1 \hat{r}_1 + g_2 \hat{r}_2) = \Re(g_1)(\hat{r}_1 - \hat{r}_2) + \hat{r}_2 \] (23)

\[ \Im(r_V) = \Im(g_1 \hat{r}_1 + g_2 \hat{r}_2) = \Im(g_1)(\hat{r}_1 - \hat{r}_2) \] (24)

Substituting (23) in (15) gives the real gains, which were calculated before\(^2\).

\[ \Re(g_1) = \frac{\hat{r}_R \cdot (\hat{r}_I - \hat{r}_2)}{\hat{r}_R \cdot (\hat{r}_I - \hat{r}_2)} \] (25)

\[ \Re(g_2) = \frac{\hat{r}_R \cdot (\hat{r}_I - \hat{r}_1)}{\hat{r}_R \cdot (\hat{r}_I - \hat{r}_2)} \] (26)

The imaginary gains are similarly found by substituting (24) in (16).

\[ \Im(g_1) = -\Im(g_2) = - \frac{\hat{r}_R \cdot \hat{r}_1}{k_{\hat{r}_R} \cdot (\hat{r}_1 - \hat{r}_2)} \] (27)

The common factor in the denominators, \( \hat{r}_R \cdot (\hat{r}_1 - \hat{r}_2) \), indicates that the panning process fails when the loudspeakers are on the left or right sides, opposite the inter aural axis. The image instability in this configuration is well known\(^6\)\(^\text{17}\), and was one of the motivations in the early development of Ambisonics. The formulation shows explicitly there is no solution.
The imaginary part of the gains, \( j \Im(g_k) \) are frequency dependent and proportional to \( 1/(jk) \), and so represent an integrating filter. This can be implemented in a real-time system with a simple one-pole low-pass filter with transfer function

\[
H(z) = \frac{b}{1 + az^{-1}}
\]  

(28)

By choosing \( a = -1 + \epsilon \) for small \( \epsilon > 0 \) the cutoff frequency can be adjusted to the low end of the ILD localisation range \( \approx 150 \text{Hz} \). The phase response then rises linearly from near \(-\pi/2\) at the cutoff frequency up to 0 at Nyquist, however the region of interest up to \( \approx 700 \text{Hz} \) is well below Nyquist with typical sampling rates \( \approx 40000 \text{Hz} \), and so the phase is approximately \(-\pi/2\) there. \( b \) is then adjusted so that the amplitude response is close to \( 1/k \) in the region of interest.

Responses for the spherical head model are calculated directly at the low frequency limit, denoted by \( 0 \text{Hz} \), based on the observations of Section II. Loudspeaker sources are modelled as plane waves, while the target source is modelled as a point source. In each case the response at the point \( r \) is calculated by evaluating the freefield at \( \frac{1}{2}r \). The frequency responses for the measured HRIRs are found by evaluating the z-transform \( H(z) \) of each impulse on the unit circle, \( H(e^{j\omega}) \), for each required angular frequency \( \omega \) (using \texttt{freqz} in Matlab). For the loudspeaker responses the HRIR used was for a source distance of 3.25 m, as before.

The binaural responses \( H_L, H_R \) for the panning simulation are calculated by mixing the individual responses using the complex gains \( g_1 \) and \( g_2 \), from (25), (26) and (27),

\[
H_L = g_1 H_{1L} + g_2 H_{2L}
\]

(30)

\[
H_R = g_1 H_{1R} + g_2 H_{2R}
\]

(31)

When using measured HRIRs, \( H_L \) and \( H_R \) accurately predict the responses that would be measured in a real panning experiment using the binaural microphone. The only assumption is linearity. Second order effects from mutual loudspeaker scattering can be ignored.

The binaural phase difference is \( \phi_{RL} = \arg(H_R/H_L) \). If necessary the phase is unwrapped beyond \( \pm \pi \) to accommodate the spatial aliasing at the top end of the ITD range \( 700-1500 \text{Hz} \). The ITD and IPD at this frequency are then given by \( \phi_{RL}/\omega \).

In the simulations the following parameters are specified: the angle \( \theta_L \) of each loudspeaker from the centre direction, the target image angle \( \theta_t \) from the centre in the horizontal plane, the target image distance from the listener \( r_I \), and the frequency. Unless otherwise stated the target image is central, \( \theta_t = 0 \), and the loudspeakers are positioned symmetrically with \( \theta_L = 45^\circ \). The ITD and ILD cues are plotted against \( \theta_N \) which is the change in horizontal angle from the central direction midway between the loudspeakers to the direction the listener is facing. The geometrical parameters are illustrated in Fig. 6.

Each plot shows three graphs. \textit{mono} shows the ITD and ILD for a single source in the target image direction. The response is based on the relative angle between the listener’s head and the target image. \textit{stereo} shows the ITD and ILD when the image is panned non-adaptively. The static gains are given by the case where the head points towards the target, which is equivalent to tangent law panning. The ITD in this case is expected to be near 0 s when the listener is facing the target image direction. The ILD should be 0 dB across the range for distant loudspeakers because the field at the listener is fixed and \( r_V \) is real valued. \textit{stereo compensated} shows the ITD and ILD when the image is panned adaptively, with \( \hat{r}_R \) varied according to the listener direction indicated by the horizontal axis.

For a given head direction \( \theta_N \) the angular error of the uncompensated or compensated stereo images is given by \( \theta_E = \theta_N - \theta'_N \), where \( \theta'_N \) is the head angle which gives the same ITD on the mono graph, as on the stereo graph in question. This can be read of the plots directly as a horizontal segment between the mono and stereo graphs.
Fig. 4: Simulated ITD vs head direction, for the spherical head model and measured head Neumann KU100. Target image $\theta_T = 0^\circ$, loudspeaker angles: $\theta_L = 45^\circ$.

(i) KU100, $r = 0.25$ m, 200 Hz  
(j) KU100, $r = 0.25$ m, 500 Hz
The directional accuracy of the adapted panning is assessed by first looking at where the uncompensated error is significant, where it exceeds the Minimum Audible Angle (MAA). The uncompensated error for a given head direction is read by taking the horizontal angle gap between the solid red (light) line at the value of the head direction, and the black line. MAA is fairly constant over the ITD frequency range, up to 1000 Hz. For lateral horizontal image displacements of 0°, 30°, 60° and 75°, representative MAAs in the ITD range are respectively 1°, 1.5°, 3°, 7°. MAA is measured under static head conditions, which suppresses the ITD localisation process. Variants of MAA under moving source and self-moving head conditions show greater sensitivity to angular changes. Even these may not capture the full sensitivity of the ITD localisation process. The comparisons are made with the more conservative MAA parameter.

Compared with directional localisation there has been relatively little research to quantify the resolution of near-field distance localisation and its relation to low frequency ILD. Some studies have investigated the just noticeable difference (JND) for ILD. Hafer reports the ILD JND using a low frequency click train, with energy from 0.1-2K Hz, across the frequency limit. A distant target is clearly benefits from compensation. There is a similar picture for ITD.

For a target at 0.25 m the compensated ITD and ILD match very well over the whole frequency range, according to the criteria already established in this section. The compensated ITD even follows the deviations of the head rotations would suggest errors in the original HRIR measurement process, since the binaural head itself is manufactured to be precisely symmetrical. This highlights the importance of precise measurement in this kind of study.

The right side binaural pressure signal is shown in Fig. 7c. In order to display the best resolution in each case. The HRIRs used for the loudspeakers are for a distance of 3.25 m, the longest available, but less than \( \infty \) m assumed by the panning method.

Figs. 4c, 5c, 4d, 5d show the case for \( r_I = 3.25 \) m. The compensated stereo ITD matches well at both frequencies. The ITD is within a JND over the whole angular range, for both frequencies (in Fig. 4c the error looks worse because the scale is different in each plot). However the ITD is clearly worsened by the proximity of the loudspeakers. This can be mostly corrected by changing the target distance to \( r_I = \infty \) m. The adapted panning method does not improve the ITD, but is needed so that the ITD is corrected.

For \( r_I = 1.0 \) m, Figs. 4e, 5e, 4f, 5f, the compensated ITD and ILD are sufficiently accurate, according to JND, although the ILD accuracy at 500 Hz is marginal. The ILD at 200 Hz clearly benefits from compensation. There is a similar picture for \( r_I = 0.5 \) m, Figs. 4g, 5g, 4h, 5h.

For \( r_I = 0.25 \) m, Figs. 4i, 5i, 4j, 5j the compensated ITD is accurate over at least the range \( \pm 30° \), for both frequencies. The compensated ILD is accurate over nearly the whole range at 200 Hz. At 500 Hz there are sections where the error exceeds the JND, although the ILD is improved by compensation over the whole range.

The previous results are evaluated for two frequencies. In the following, the mono and stereo compensated cases are compared across a frequency range of 100 Hz - 700 Hz, for several head positions. In each case the target image is straight ahead, \( \theta_I = 0° \), at a range \( r = 0.5 \) m. The HRIRs used for the stereo loudspeakers have \( r = 3.25 \) m, the longest range available.

Fig. 7a shows that the ITD of the compensated reproduction matches the mono source very well over the whole frequency range, according to the criteria already established in this section. The compensated ITD even follows the deviations of the mono source ITD, although in the low frequency model the ITD is constant. The compensated ILD shown in Fig. 7b is within JND below 400 Hz, then the error increases towards 700 Hz. The slight elevation in the ILD at lower frequencies can be explained by the stereo loudspeakers being closer than infinity, which is the range assumed by the CAP method. The ILD asymmetry displayed across the head rotations would suggest errors in the original HRIR measurement process, since the binaural head itself is manufactured to be precisely symmetrical. This highlights the importance of precise measurement in this kind of study.

The right side binaural pressure signal is shown in Fig. 7c.

Simulations with measured HRIRs show that, and the orientation of the listener’s head, without knowledge according to the directions of the image and loudspeakers, range. The ITD and ILD cues are simultaneously controlled special effect. It may be useful to exaggerate the ILD cue, for example for distance control overall ILD match could be improved by warping the image distance control $r_1$, without distorting the ITD significantly. It may be useful to exaggerate the ILD cue, for example for special effect.

VIII. SUMMARY

A complex panning method was described, based on the reproduction of low frequency cues for image direction and range. The ITD and ILD cues are simultaneously controlled according to the directions of the image and loudspeakers, and the orientation of the listener’s head, without knowledge of head size. Simulations with measured HRIRs show that, considering frequencies representing the core ILD frequency range, stable images can be produced up to 0.25 m range. The initial stereo implementation is being extended to a flexible multi-channel framework, as part of a flexible object-based system.

IX. ACKNOWLEDGEMENTS

This work was supported by the Engineering and Physical Sciences Research Council (EPSRC) “S3A” Programme Grant EP/L000539/1, and the BBC Audio Research Partnership. No new data was created in this work.

REFERENCES

Dylan Menzies Dr Dylan Menzies is a Senior Research Fellow in the Institute of Sound and Vibration, at the University of Southampton. Areas of interest include spatial audio synthesis and reproduction, sound synthesis for virtual environments, and musical synthesis and interfaces. He holds a PhD in Electronics from the University of York, an MA in Mathematics from Cambridge University, and has worked as a research engineer for several companies including Sony Professional Audio.
Filippo Maria Fazi graduated in Mechanical Engineering from the University of Brescia (Italy) in 2005. He obtained his PhD in acoustics from the Institute of Sound and Vibration Research (ISVR) of the University of Southampton, UK, in 2010, with a thesis on sound field reproduction. In the same year, he was awarded a research fellowship by the Royal Academy of Engineering and by the Engineering and Physical Sciences Research Council. He is currently an Associate Professor at the University of Southampton. Dr Fazi’s research interests include acoustical inverse problems, multi-channel systems, virtual acoustics, microphone and loudspeaker arrays.
