Abstract
Alzheimer’s disease (AD) is a public health priority for the 21st century. Risk reduction currently revolves around lifestyle changes with much research trying to elucidate the biological underpinnings. We show that self-report of parental history of Alzheimer’s dementia for case ascertainment in a genome-wide association study of 314,278 participants from UK Biobank (27,696 maternal cases, 14,338 paternal cases) is a valid proxy for an AD genetic study. After meta-analysing with published consortium data (n = 74,046 with 25,580 cases across the discovery and replication analyses), three new AD-associated loci (P < 5 × 10−8) are identified. These contain genes relevant for AD and neurodegeneration: ADAM10, BCKDK/KAT8 and ACE. Novel gene-based loci include drug targets such as VKORC1 (warfarin dose). We report evidence that the association of SNPs in the TOMM40 gene with AD is potentially mediated by both gene expression and DNA methylation in the prefrontal cortex. However, it is likely that multiple variants are affecting the trait and gene methylation/expression. Our discovered loci may help to elucidate the biological mechanisms underlying AD and, as they contain genes that are drug targets for other diseases and disorders, warrant further exploration for potential precision medicine applications.

Introduction
The genetic epidemiology of late-onset Alzheimer’s disease (LOAD) has advanced over the last decade1, with >20 independent loci associated with the disease in addition to APOE2. Presently, the largest meta-analytic genome-wide association study (GWAS) for LOAD employed a two-stage study design. First, 17,008 cases were compared to 37,154 controls. A total of 11,632 single-nucleotide polymorphisms (SNPs) with P < 1 × 10−3 from this meta-analysis were included in the second stage that compared 8,572 cases to 11,312 controls. A meta-analysis of the SNPs included in stages 1 and 2 was also performed3.

One difficulty in traditional studies of AD is case ascertainment4—either directly for prevalent cases or indirectly through prospective cohort studies for incident cases. A recent GWAS study on a subset of the UK Biobank cohort used information from family history (parent or first-degree relative with AD or dementia) as a proxy-phenotype for the participants5. When meta-analysed with the GWAS summary data highlighted above3, four new loci were identified.

The UK Biobank proxy-phenotype AD question, which is used here, does not incorporate biomarker data that are required for a clinical diagnosis. However, it is easy to administer at scale and we show that it has a near-unit genetic correlation with the AD results from the LOAD meta-analysis3, where many of the samples also lacked a confirmed diagnosis by biomarker levels or autopsy.

In the present study, we related proxy-phenotype information on dementia (i.e., reporting a parent with Alzheimer’s dementia or dementia) to genetic data from...
314,278 individuals from the UK Biobank cohort to identify new AD-associated loci. This sample includes individuals from the previous proxy-phenotype AD study by Liu et al. GWA studies were conducted separately for maternal and paternal AD due to a 1.7-fold difference in disease prevalence—9.6% and 5.5%, respectively. The summary statistics from these models were meta-analysed with those from the largest publicly available case-control study. Sensitivity analyses showed that an overlap of controls in the maternal and paternal GWAS did not bias the results. Genetic correlation analysis showed the self-reported measure of parental AD to be an accurate proxy for clinical diagnosis, validating the global meta-analysis. In addition, we tested for causal evidence of our SNP—AD associations being mediated through gene expression and DNA methylation in the prefrontal cortex.

Subjects and methods

UK Biobank cohort

UK Biobank data (http://www.ukbiobank.ac.uk) were collected on over 500,000 individuals aged between 37 and 73 years from across Great Britain (England, Wales and Scotland) at the study baseline (2006–2010), including health, cognitive and genetic data.

The Research Ethics Committee (REC) granted ethical approval for the study—reference 11/NW/0382—and the current analysis was conducted under data application 10,279.

Genotyping

Genotyping details for the UK Biobank cohort have been reported previously. Briefly, two custom genotyping arrays were utilised with 49,950 participants typed using the UK BiLEVE Axiom Array and 438,427 participants typed using the UK Biobank Axiom Array. The released genotyped data contained 805,426 markers on 488,377 individuals. Imputed genotypes were supplied with those from the largest publicly available case-control study. Phenotypes

Family history of Alzheimer’s disease was ascertained via self-report. Participants were asked “Has/did your father ever suffer from Alzheimer’s disease/dementia?” and “Has/did your mother ever suffer from Alzheimer’s disease/dementia?” Self-report data from the initial assessment visit (2006–2010), the first repeat assessment visit (2012–2013) and the imaging visit (2014+) were aggregated with exclusions made for participants whose parents were: aged under 60 years; dead before reaching age 60 years; without age information. After merging with the genetic data, this left 27,696 cases of maternal AD and 14,338 cases of paternal AD with 260,980 controls. There were 314,278 instances where AD information was available on at least one parent. Given the expected difference in disease prevalence due to sex differences in longevity—AD prevalence was 1.7-fold higher in mothers compared to fathers—GWA studies were performed separately for maternal and paternal AD.

Genome-wide association study

The GWA studies were conducted using BGENIE. The outcome variable was the residuals from a linear regression model of maternal or paternal AD on age of parent at death or at time of the offspring’s self-report, assessment centre, genotype batch, array and 40 genetic principal components. The predictor variable was the autosomal SNP and an additive model was considered.

The GWAS linear regression coefficients were converted to odds ratios using observed sample prevalences of 0.096 and 0.055 for maternal and paternal AD, respectively. Subsequently, the log-odds were multiplied by two so that the effect sizes are reported on the same scale as a traditional case-control design. Briefly, the conversion to odds ratios uses the following equation, derived in Lloyd-Jones et al., where $k$ = disease prevalence, $p$ = population allele frequency and $\beta$ = the estimated SNP regression coefficient on the binary disease scale from the GWAS: $OR = \left(1 - \frac{k + \beta_1 - \beta_1 p}{1 - k + \beta p}\right) \left(1 - k + \beta_1 p\right)$.

SEs for the log-odds were then calculated based on the adjusted OR and the $P$-value from the initial GWAS (Supplementary Note 1). The ORs and SEs were then carried forward to a SE-weighted meta-analysis in METAL, first to create a UK Biobank parental meta-analysis, and then with the stage 2 summary output from the International
Genomics of Alzheimer’s Project (IGAP) study, and the stage 1 output for the SNPs that did not contribute to stage 2. Linkage disequilibrium score (LDSC) regression was used to estimate the genetic correlation between the maternal and paternal AD GWAS results and to test for residual confounding in the meta-analysis by examining the LDSC intercept.

The number of independent loci from the meta-analysis was determined by using the default settings in FUMA. Independent lead SNPs had \( P < 5 \times 10^{-8} \) and were independent at \( r^2 < 0.6 \). Within this pool of independent SNPs, lead SNPs were defined as those in LD at \( r^2 < 0.1 \). Loci were defined by combining lead SNPs within a 250 kb window and all SNPs in LD of at least \( r^2 = 0.6 \) with one of the independent SNPs. A gene-based analysis was carried out on all SNP output using the MAGMA software, with default settings (SNP-wise (mean) model for each gene), and assuming a constant sample size for all genes. A Bonferroni-adjusted \( P \)-value of 0.05/18,251 = 2.7 \( \times 10^{-6} \) was used to identify significant genes. The 1000 genomes phase 3 data were used to map LD in both the independent locus and MAGMA analyses.

Summary data-based Mendelian randomisation

To test for pleiotropic associations between SNPs and AD and gene expression/DNA methylation in the brain, summary data-based Mendelian randomisation (SMR) was performed. GWAS summary output from the meta-analysis of UK Biobank and IGAP (sample size specified as 314,278 + 74,046 = 388,324) were included along with expression Quantitative Trait Loci (eQTL) summary output from the Common Mind Consortium, which contains data on >600 dorsolateral prefrontal cortex samples, and DNA methylation QTL summary output on 258 prefrontal cortex samples (age >13). The reference genotypes were based on the Health and Retirement Study, imputed to the 1000 Genomes phase 1 reference panel. SNP exclusions included: imputation score <0.3, Hardy–Weinberg \( P \)-value < 1 \( \times 10^{-6} \) and a minor allele frequency <0.01. Related individuals, based on a genomic-relationship matrix cutoff of 0.05, were removed. Two sets of eQTL summary data were considered (1) after adjustment for diagnosis, institution, sex, age of death, post-mortem interval, RNA integrity number (RIN), RIN\(^2\), and clustered library batch (2) with additional adjustments for 20 surrogate variables to account for additional possible confounders. Five ancestry vectors were included as covariates in the eQTL analyses. Further details are available at: https://www.synapse.org/

Results

UK Biobank GWAS

There were 27,696 cases of maternal AD (260,980 controls, prevalence of 9.6%) and 14,338 cases of paternal AD (245,941 controls, prevalence of 5.5%) in the UK Biobank. The genetic correlation between maternal and paternal AD was not significantly different from unity (\( r_g = 0.71 \), SE 0.43), although the SE is large. Both traits had a high genetic correlation with the case-control summary output from the IGAP study: \( r_g \) with maternal and paternal AD was 0.91 (SE 0.24) and 0.66 (0.39), respectively, both not significantly different from unity but with large SEs.

Prior to meta-analysing the UK Biobank parental summary statistics with the IGAP output, we investigated the influence of overlapping proxy controls in UK Biobank. The \( P \)-values from a single GWAS of parental AD status (0, 1 or 2 parents with AD) correlated 0.99 with those from a meta-analysis of separate maternal AD and paternal AD; the regression of \(-\log_{10} P\)-values on each other gave an intercept of 0 and a slope of 1. A meta-analysis of the summary statistics from the maternal and paternal results is therefore essentially equivalent to the analysis of parental AD status. The linear regression effect sizes from the GWAS were converted to odds ratios prior to the meta-analysis.

UK Biobank paternal and maternal meta-analysis

Six genome-wide significant loci were identified in the UK Biobank paternal and maternal GWAS meta-analysis (Supplementary Table 1, GWAS summary statistics available at www.ccace.ed.ac.uk/node/335). All were located in established AD loci. The top lead SNPs were rs679515 \( (P = 5.3 \times 10^{-5}, \text{chr1, CRI locus}) \), rs6733839 \( (P = 1.1 \times 10^{-27}, \text{chr2, BIN1 locus}) \), rs7384878 \( (P = 1.3 \times 10^{-10}, \text{chr7, PILRA locus}) \), rs3851179 \( (P = 1.8 \times 10^{-12}, \text{chr11, PICALM locus}) \), rs3845261 \( (P = 4.0 \times 10^{-8}, \text{chr17, ZNF232 locus}) \) and rs10119 \( (P = 1.1 \times 10^{-307}, \text{chr19, APOE/TOMM40 locus}) \). The chromosome 17 locus is ~100 kb from the SCIMP gene-variant identified by Liu et al.

UK Biobank parental and IGAP meta-analysis

The meta-analysis of the maternal and paternal AD history in UK Biobank with the IGAP data identified 69 lead SNPs and 218 independent significant SNPs with \( P < 5 \times 10^{-8} \) from 21 genomic risk loci. The majority (\( n = 42 \)) through which a cis SNP may be acting on the outcome, AD. The heterogeneity in dependent instruments (HEIDI) \( P \)-value indicates evidence for a single causal SNP (effect on AD is mediated through the transcript/methylation site if \( P > 0.05 \)) or different SNPs affecting AD and the transcript/methylation site if \( P < 0.05 \).
of the lead SNPs were located in the gene-dense APOE/TOMM40 locus on chromosome 19 (Fig. 1 and Supplementary Tables 2 and 3; GWAS summary statistics are available for the 7,795,605 meta-analysed SNPs online: www.ccace.ed.ac.uk/node/335). The LDSC regression intercept term from the meta-analysis summary output was 1.021 (SE 0.0099), and around 85% of the genomic inflation ($\lambda = 1.09$) was due to the polygenic signal, rather than sources of confounding including population stratification and cryptic relatedness.

Novel genome-wide significant loci

Of the 21 significant risk loci, three were novel (Table 1 and Supplementary Figures 1–3). The top lead SNPs were: rs593742 (ADAM10, locus chr15:58873555–59120077); rs889555 210 (BCKDK/KAT8, locus chr16:30916129–31155458); and rs6504163 (ACE, locus 211 chr17:61545779–61578207).

Replication of IGAP SNPs

Fifteen of the 21 previously reported SNPs ($P < 5 \times 10^{-8}$) associated with AD were genome-wide significant ($P < 5 \times 10^{-8}$) in the current meta-analysis, with four other SNPs (rs2718058, rs10838725, rs17125944 and rs10498633) having $P < 1 \times 10^{-5}$ (Supplementary Table 4). The MEF2C variant, rs190982, had a meta-analysis $P$-value of $7.2 \times 10^{-3}$ and rs8093731 (a DSG2 variant), which was genome-wide significant in stage 1 but not stage 2 of IGAP, had a meta-analysis $P$-value of 0.07. There was complete sign-concordance between UK Biobank and IGAP for all 21 SNPs (Supplementary Table 4). The odds ratios between the maternal and paternal analysis for the top 21 IGAP SNPs were correlated $r = 0.91$. Both also correlated highly with the effect sizes reported in the IGAP analysis ($r = 0.87$ and 0.84, respectively).

Gene-based analysis

A total of 92 genes were significant at a Bonferroni threshold of $P < 2.7 \times 10^{-6}$ (Supplementary Table 5). Gene ontology analysis, using a Fisher exact test to compare the number of significant genes in each gene set with the expected number, showed significant enrichment for 46 gene sets, including those linked to the regulation of amyloid-beta, neurofibrillar tangle assembly, immune
response, and cholesterol and lipid transport (Supplementary Table 6).

Summary data-based Mendelian randomisation

Pleiotropic associations between AD and gene expression in the brain were tested using SMR\(^7\). GWAS summary data for AD were taken from the UK Biobank and IGAP meta-analysis. eQTL summary data came from the Common Mind Consortium (\(n > 600\) dorsolateral prefrontal cortex samples: data set 1 adjusted for age at death, sex and institution; data set 2 made additional adjustments for 20 surrogate variables). MethQTL data came from 258 dorsolateral prefrontal cortex samples (participants aged 13 years and older—adjustments were made for the first 5 genetic MDS components and first 11 methylation PCs\(^18\)). We found evidence of brain expression and DNA methylation associated with AD in the TOMM40 gene (part of the APOE/TOMM40 cluster on chromosome 19) in both the second eQTL model and also in the methQTL model (Supplementary Tables 7–9). However, the HEIDI \(P\)-values were <0.05 for both analyses, indicating that the associations were unlikely to be driven by a single causal variant affecting both expression/methylation and AD.

Different top QTL SNPs in TOMM40 were identified in the two analyses: rs760136 and rs7259620 although they were in perfect LD in European samples\(^19,20\) (\(R^2 = 1.00\)). The SNPs have differing LD patterns with the \(rs6448453\) allele defining SNPs, rs7412 (\(R^2 = 0.001, D' = 0.03\)) and rs429358 (\(R^2 = 0.15, D' = 1.0\)). A significant SMR association with HEIDI \(P\)-value >0.05, indicating pleiotropy, was observed for \(KAT8\) in the eQTL analysis (Supplementary Table 8 and Supplementary Figure 4) and for \(EXOC3L2\) (chr19, \(APOE/TOMM40\) locus) and \(STAG3\) (chr7, \(PLRA\) locus) in the methQTL analysis (Supplementary Table 9 and Supplementary Figures 5 and 6).

Discussion

Using recently established proxy-phenotype methods for case ascertainment, we show this approach to be valid in GWAS of AD. Meta-analysing the proxy-phenotype summary statistics from UK Biobank with those from a case–control study (IGAP), we identified three new genome-wide significant loci that contain several relevant genes.

\(ACE\) determines levels of angiotensin II, which has trophic actions within the brain and contributes to the regulation of cerebral blood flow\(^21\). Previous meta-analyses of candidate gene studies identified variants within \(ACE\) to be associated with AD, though not at genome-wide significance\(^22,23\). \(ACE\) variants have also been linked to atrophy of the hippocampus and amygdala\(^24\), and CSF-ACE protein levels correlate with CSF tau and phosphorylated tau\(^25,26\).

\(ADAM10\) is involved in the cleavage of amyloid-beta precursor protein\(^27\), which is involved in the deposition of amyloid beta, a major neurological hallmark of AD. \(ADAM10\) has been proposed as potential therapeutic agent in AD therapy\(^27,28\). Rare variants in \(ADAM10\) have also been linked to LOAD\(^29\). The \(BCKDK/KAT8\) locus contains the \(VKORC1\) gene, which was a genome-wide significant gene-based finding (\(P = 3.4 \times 10^{-8}\)). The \(VKORC1\) variant, rs9923231, whose T allele was suggestively associated with an increased risk of AD (\(P = 6.9 \times 10^{-8}\)), is strongly associated with the need for a reduced dose of warfarin anticoagulation\(^30,31\). \(KAT8\) is regulated by \(KANSL1\), which has been linked to AD as a genome-wide significant finding in \(APOE\) e4-negative individuals\(^32\).

Our cutoff for relatedness of 0.025 in UK Biobank was very stringent, in particular since disease status was on parents of genotyped individuals, so that correlations in proxy-phenotypes from relatives (e.g., cousins) are likely to be very small. When we used a more relaxed threshold of 0.4 (excluding first-degree relatives only), we increased our sample size to 385,869 and found four additional loci and top lead SNPs: rs4575098, \(P = 2.7 \times 10^{-8}\), \(ADAMTS4\) (chr1:161097241–161156033); a gene desert on chr4 (rs6448453, \(P = 1.2 \times 10^{-9}\), chr4:11026028–11040406) that is ∼400 kb from the \(CLNK\) gene; in \(CCDC6\) on chr10 (rs1171812, \(P = 3.5 \times 10^{-8}\), chr10:61631416–61710540); and in a poorly annotated region on chr16 (rs12444183, \(P = 5.3 \times 10^{-9}\), chr16:81773003–81773816), proximal to the \(PLCG2\) gene. The corresponding \(P\)-values for these four lead SNPs in the GWAS meta-analysis with the more stringent relatedness cutoff were \(P = 8.4 \times 10^{-8}, 5.9 \times 10^{-8}, 5.7 \times 10^{-7}\) and \(7.4 \times 10^{-8}\), respectively.

The gene-set enrichment analysis implicated pathways involved in AD neuropathology (amyloid and neurofibrillary tangles) in addition to immune response, lipid and cholesterol metabolism, as previously reported in a gene-set analysis on the IGAP data\(^33\). A separate gene-set analysis on the meta-analysed paternal and maternal summary statistics from UK Biobank showed a highly overlapping set of enriched pathways (Supplementary Table 10).

An integrative analysis of eQTL and methQTL with the GWAS summary data identified one previously identified AD gene, \(TOMM40\), as having its gene expression and methylation levels associated with AD. The most parsimonious explanation of these results is the existence of multiple causal variants, some affecting AD and others affecting expression or methylation. A previous SMR analysis of AD and LDL cholesterol identified evidence of 16 pleiotropic SNPs, 12 of which were located in the \(APOE\) region\(^34\). Given the involvement of immunity in the aetiology of AD, as highlighted by the pathway analysis, it may be relevant to consider immune cells, such as monocytes, for the SMR analysis.
The main strength of the study is the proxy-phenotype approach, which resulted in over 42,000 proxy cases for the GWAS analysis. However, the question used to determine parental AD status may have resulted in some responders being unable to discriminate Alzheimer’s disease and dementia from other dementia sub-types, which have different presentations and genetic architectures. This method of proxy-case ascertainment may have influenced the loci uncovered. Parental dementia status is partly dependent on longevity, with age being the biggest risk factor for AD. We partially controlled for this by excluding participants whose parents were younger than or died prior to reaching the age of 60 years when AD incidence is extremely low. The misclassification of case status via incorrect informant reporting will have reduced the power to detect true effects. This, along with a possible winner’s curse effect for the IGAP study, might explain the reduction in the meta-analytic odds ratios compared to those previously reported.

Conclusion

We identified three new AD-associated loci that have known and putative biological processes associated with Alzheimer’s disease. These findings help to elucidate the biological mechanisms underlying AD and, given that some loci (VKORC1, ACE) are existing drug targets for other diseases and disorders, warrant further exploration for potential precision medicine and clinical trial applications.
