Abstract

This paper examines the effect of chronotype on the delinquent credit card payments and stock market participation through preference channels. Using an online survey of 455 individuals who have been working for 3 to 8 years in companies in mainland China, the results reveal that morningness is negatively associated with delinquent credit card payments. Morningness also indirectly predicts delinquent credit card payments through time preference, but this relationship only exists when individuals’ monthly income is at low and average level. On the other hand, financial risk preference accounts for the effect of morningness on stock market participation. Consequently, an additional finding is that morningness is positively associated with financial risk preference, which contradicts previous finding in the literature. Finally, based on the empirical evidence, we discuss the plausible mechanisms that may drive these relationships and the implications for theory and practice. The current study contributes to the literature by examining the links between circadian typology and particular financial behaviour of experienced workers.
1. Introduction

Circadian rhythm is a time-based oscillation in physiological and biological functions that reflect a cycle of approximately 24 hours. For humans and animals, the inner biological clock, which is situated in the suprachiasmatic nuclei of the hypothalamus, regulates this rhythm Piffer et al. (2014). Sequentially, the hypothalamus secretes melatonin Nelson (2011). There is board individual heterogeneity in circadian rhythms, which can be identified by biological markers, such as sleep-wake patterns (Andretic et al., 2008), body temperature (Baehr et al., 2000; Kerkhof and Van Dongen, 1996), and genes (Franken and Dijk, 2009). The sleep-wake cycle can be measured as circadian chronotypes, also known as morningness-eveningness, which are distributed normally on a continuum (Natale and Cicogna, 2002), allowing the categorization of individuals into three groups: morning chronotype, neither type, and evening chronotype. Morning chronotype individuals, also known as “larks”, are more likely to wake up in the early morning and to go asleep in the early evening as well. Evening chronotype individuals, also known as “owls”, prefer to go to sleep late in the evening and to wake up later in the day (Horne and Ostberg, 1976).

For the last two decades, there has been increasing interest research into the effect of morningness-eveningness on multiple facets of life. Studies have reported links between the circadian chronotypes and work shifts (McLaughlin et al., 2008), jet lag (Waterhouse et al., 2022; Flower et al., 2003), cognitive efficiency (Colquhoun, 1971), cognitive style (Sternberg and Zhang, 2014), personality traits (Antúnez et al., 2014), academic performance (Piffer et al., 2014), mental disorders (Martin et al., 2012; Levandovski et al., 2011), and life habits (Achilles, 2003). Based on these findings, we note that the circadian typologies influence psychological perspectives and behaviour, but mainly in the aspects of work, education, health. Very few researchers have examined the association between morningness-eveningness and financial behaviour. The effect of the circadian rhythm on financial well-being is important because financial well-being contributes positively to general life satisfaction (Kruger, 2011).

The first goal of this study is to investigate whether the circadian typology influence financial behaviour, especially delinquent credit card payments and stock market participation. First, revolving credit borrowers who do not entirely pay off their loans after the monthly deadline or miss payments have a larger amount of credit debt, compared to those who pay off such loan on time. From a financial perspective, delinquent credit card payments are not of benefit to long-term financial health because adopting the habit of making loan payment late leads to accumulated outstanding debt (Kim and DeVaney, 2001). Such consumers are more likely to have incomplete credit card debts, which in the short run leads to higher interest rates, financial penalties, and higher outstanding balances (Elliehausen et al., 2007). Investigating the effect of morningness-eveningness on delinquent credit card payments could provide practical implications, such as interventions that prevent this behaviour or that help break the habit of not paying back loans according to monthly time schedule. Second, participation in the
The stock market is essentially a financial decision (Almenberg and Dreder, 2015), and it might be financially harmful if one refuses to take part in the stock market over the long term. The reason is that equity premium can provide long-term benefits for personal savings, which in turn influence personal financial well-being.

The second goal of the present study is to investigate the possible mechanisms through which morningness-eveningness influences delinquent credit card payments and stock market participation. We draw on the theories of risk preference and time preference, in order to provide a richer explanation regarding the likely channels. The first reason is that morning-types are positively associated with future time preference (Díaz-Morales and Sánchez-Lopez, 2008; Stolarski et al., 2013), while Meier and Sprenger (2010) reported that present-biased individuals tend to have higher revolving credit balances compared with future-oriented individuals. Hence, the time perspective appears to be a possible channel between the circadian typology and incomplete monthly credit debt payments. The second reason is that morning larks are negatively associated with risk attitudes (Wang and Chartrand, 2015), while risk preference is a predictor of the probability of participating in stock market (Dohmen et al., 2011). Therefore, we anticipate risk preference would be a possible channel between chronotypes and owning equity. In addition, income may moderate the indirect effects of the circadian typologies on the likelihood of delinquent credit card payments and investments in stock because income is a determinant of outstanding balances among credit card revolvers (Kim and DeVaney, 2001; Calem and Mester, 1995) and is associated with risk preference (Tanaka et al., 2010).

We launched an online survey and received 455 valid questionnaires from employees who have 3 to 8 years of working experience. We used the Composite Scale of Morningness (CSM) (Smith et al., 1989) to measure the circadian chronotypes, measured the time perspective by following Finke and Huston (2013), and drew on a single question to measure financial risk preference, as proposed by Dohmen et al. (2011). We used regression and path analysis to examine the hypothesized relationships and the results revealed significant findings. First, the results indicate that morningness inhibits the likelihood of conducting late payments or missing payments on credit card debt. Second, time preference partially mediates the relationship between the morning chronotype and delinquent credit card payment, but this indirect effect only exists when subjects’ income level is at average and low levels, for the path from time preference to incomplete credit card payment. The present study is of help to put forward the underlying mechanism and the conditions of the association between the circadian typology and delinquent credit card payment. Furthermore, another novel finding is that financial risk preference fully mediates the link between morningness and the probability of owning equity. Hence, the current study helps to elucidate the unique channel and mechanism through which morning type exert influence on stock market participation. Furthermore, as those characteristics have been found in experienced workers, the results could be a valuable tool for financial professionals who should consider circadian rhythms when developing and introducing financial products or financial services for the morning-type.
intermediate-type, and evening-type population. Future research could enhance the study of the relationship between morningness-eveningness, preference constructs, and financial behaviour by using a wider population, such as adding an aging group, sampling from different countries. In addition, longitudinal studies would be particularly powerful for testing the proposed relationships.

We organize the present paper as follows: In Section 4.2, we given a literature review to build up the hypothesized frameworks to examine the relationship between circadian chronotypes, risk and time preference, and financial behaviour. In Section 4.3, we describe sampling method, measurements of data, descriptive statistics of data, and econometric models. In Section 4.4, we report the results. Section 4.5 is discussion, which provides theoretical and practical implications as well as some limitations of our research. We conclude in Section 4.6.

2. Literature review

2.1 Overview of theoretical rationale

In the context of personality psychology, circadian rhythm varies among individuals who can be classified as morning-types, neither-types, and evening-types. In particular, morning larks wake up in the early morning, achieve their peak performance physically and mentally in the early morning, and go to bed early in the evening. In contrast to morning larks, evening owls prefer to wake up late in the morning and go to bed late in the evening, and their peak performance is later in the day or in the evening (Cavallera and Giudici, 2008; Adan et al., 2012).

Researchers usually elicit circadian chronotypes by using self-reported survey questions (Randler, 2009). The first and most commonly used measure is the Morningness-eveningness questionnaire (MEQ) proposed by Horne and Ostberg (1976). Nevertheless, MEQ has been criticized due to its length (19 items) (Torsvall and Åkerstedt, 1980). Its value arranges from 20 to 75. Smith et al. (1989) developed a short composite scale with 13 items (CSM). The authors classified the values on their morningness-eveningness scale into three groups using the cut-off points, with morning types (40 and above), intermediate types (23-43), and evening types (22 or fewer). More recently, Randler et al. (2016) proposed a new measure with 15 items, termed morningness–eveningness-stability-scale improved (MESSi), and Faßl et al. (2018) provided the evidence to validate this scale. We will use the CSM scale for the Chinese population to measure circadian chronotypes and to validate the Chinese version of CSM.

The determinants of circadian typologies are various, including demographics, environmental, and biological and genetic factors (Cavallera and Giudici, 2008; Adan et al., 2012). First, age is a demographic factor that is positively associated with a morning orientation after the end of adolescence (Kim et al., 2010; Merikanto et al., 2010). Gender is another demographic factor; males are more likely
to be evening owls, while females appear to be more morning-oriented (Adan and Natale, 2002). Second, the photoperiod at birth is an environmental factor that influences circadian chronotypes. Individuals who were born in autumn and winter are prone to be morning-types, whereas those born between spring and autumn are more likely to be evening owls (Mongrain and Paquet, 2006). Another environmental factor is the longitude and latitude of residence. People who live in the East and North are more likely to be morning larks (Natale and Di Milia, 2011). Third, the biological expression of individual differences in circadian rhythms reflects that the acrophase of melatonin for morning larks occurs in the early morning, compared to evening owls (Duffy et al., 1999). Genetic factors also explain the variance in individual circadian rhythms, as a single nucleotide polymorphism positioned at the 3’ flanking area of humans’ CLOCK gene can be an interpreter of morning orientation for ordinal grownups (Katzenberg et al., 1998).

Circadian typology has been documented as a key individual characteristic in life, which influences cognitive performance, work performance (Sõõru et al., 2017) and psychological well-being (Carvalho et al., 2018). Prior research reported that the cognitive performance of morning-types is lower than that of evening-types (Roberts and Kyllonen, 1999). However, evening owls are better at intermediate memory (Natale and Lorenzetti, 1997). Circadian typology is also associated with psychiatric disorders, personality traits (Antúnez et al., 2014; Cavallera and Giudici, 2008), work shifts (Di Milia and Muller, 2012), and life habits (Achilles, 2003; Tankova et al., 1994). Therefore, previous studies have explored the effects of circadian rhythms on behaviour in the contexts of education, work, and health. However, to the best of our knowledge, very few studies have examined the effect of circadian rhythms on financial behaviour, such as revolving credit balance and stock market participation.

A credit card is a tool for convenient payment (Garman and Forgue, 2012). Credit card holder who do not pay off the entire loan before the monthly deadline or who miss the payments have higher amounts of credit card debt compared with those who pay off in time. Kim and DeVaney (2001) highlighted that poor loan payment habits drive the accumulation of outstanding debt. Hence, consumers who have such habits are more likely to have delinquent credit card payment, which in the short-run leads to higher interest rates, financial penalties, and higher outstanding balances (Elliehausen and Christopher, 2007), and in the long-run harms consumers’ financial well-being. If circadian rhythms can predict the possibility of having delinquent credit card debt, a better understanding of this characteristic may help to improve borrowing behaviour and creditworthiness, which in turn contribute to a better financial situation. For example, if evening-types are positively associated with the possibility of having a revolving credit balance, shifting into morning circadian rhythm could be a helpful intervention, as morning larks are more conscientious and proactive about achieving long-term goals.

Stock market participation is an important financial decision (Almenberg and Dreber, 2015). It can be costly for individuals who do not invest in stocks because the stock premium can be a key predictor of
the long-term benefits for personal savings, which in turn determine the status of personal financial well-being. Prior research has proposed a number of external and internal factors, which predict the likelihood to invest in stock, such as social interaction (Hong et al., 2004), awareness (Guiso and Jappelli, 2005), financial literacy (Van Rooij et al., 2011), IQ (Grinblatt et al., 2011), health (Rosen and Wu, 2004; Bogan and Fertig, 2013), gender (Almenberg and Dreber, 2015), and access to Internet (Bogan, 2008). Given the evidence that circadian rhythm is driven by biological and genetic factors and that they remain stable over time (Piffer et al., 2014), we examine whether morningness-eveningness influences the willingness to participate in the stock market.

Since these behaviour are financially meaningful, investigating the effect of circadian rhythms on these financial behaviour is our research goal.

2.2 Conceptual model and hypotheses development

Morning larks and delinquent credit card payments (H1)

The first goal of the present paper is to explore the relationship between morning-types and revolving credit card debt. In the literature, Randler (2009) reported that morning larks are prone to be more proactive than evening owls, which provides an inspiring starting point. In particular, proactivity is the willingness and capability to alter a situation to make it in one’s favour (Kirby and Kirby, 2006), and it can be influential in a wide range of circumstances. For example, a proactive personality connects to job autonomy through self-efficacy (Parker et al., 2006); proactive individuals attain more success in careers, earnings (Seibert et al., 1999), and studying performance (Kirby et al., 2002).

Although, few studies have examined the role of the circadian chronotypes in revolving credit card debt, by integrating the role of proactivity, it is reasonable to anticipate the negative association. On the one hand, morning-types are more proactive than evening-types, and on the other hand, proactivity describes the extent of which individuals anticipate, and minimize the negative influence of possible future problems, avoiding them completely if possible (Aspinwall et al., 2002; Aspinwall et al., 2003). At the same time, unpaid balances on credit cards represents such a negative potential problem that will increase consumers’ interest rates if they do not pay off their monthly balances on time (Hazembuller et al., 2007). Therefore, we expect that morning larks are much less likely to be unable to pay off their monthly credit card balance entirely. Accordingly, we propose:

Hypothesis 1: Morning-types are negatively associated with delinquent credit card payments. Specifically, compared to intermediate- and evening-types, morning larks are less likely to have unpaid credit card debt.

The mediating role of time preferences (H2)
To provide a richer explanation for morning chronotype’s influence on delinquent credit card payments, we use theories of time perspective (i.e., future-oriented or present-biased). An individual’s conception of time helps them to organize each life event in a methodical and anticipated rhythm (Milfont and Schwarzenthal, 2014). According to the neurological explanation, decisions that are expected to result in a future award in the region of the rational prefrontal cortex, whereas decisions that are expected to result in a present award occur in the emotional limbic region in the brain (Benedetti et al., 2007). Present-oriented individuals appear to seek immediate gratification at the cost of future utility. In contrast, future-oriented individuals are more likely to delay gratification in order to achieve long-run goals (Fudenburg and Levine, 2006).

Prior studies have reported a relationship between circadian rhythms and time perspectives. In particular, morning-types are positively associated with future time preference (Díaz-Morales and Sánchez-Lopez, 2008; Stolarski et al., 2013; Milfont and Schwarzenthal, 2014) and the processing channel is self-control (Milfont and Schwarzenthal, 2014), as more self-control results in reasonable decisions to delay gratification and to concentrate on achieving future goals. On the other hand, previous research has also suggested a link between time preference and credit card debt. Meier and Sprenger (2010) reported that present-discounting individuals have higher amount of revolving credit balances, compared with future-oriented individuals. Their results are also robust when changing the method of calculating the time perspective and the sample selection criteria. Therefore, to examine whether time discounting explains the association between morning-types and delinquent credit card payments, we propose:

Hypothesis 2: Time preference mediate the relationship between morning-types and delinquent credit card payments.

The moderating role of monthly income in a second-stage moderated mediation model (H3 and H4)

We have proposed that morningness influences the likelihood of delinquent credit card payment through time discounting, and we anticipate the strength of this mediating effect to vary according to the level of income in the path from time preference to delinquent credit card payments.

The life-cycle model assumes that consumers will maximize the utility from lifetime consumption (Ando and Modigliani, 1963), and Bryant (1990) proposed that borrowing is intended to change future resources into present resources with the purpose of increasing present consumption. Income is one determinant of outstanding credit card balances (Kim and DeVaney, 2001; Calem and Mester, 1995). These researchers reported that income is positively associated with the amount of outstanding credit card debt because the purpose of borrowing is to satisfy individuals’ consumption demand throughout
their lifetime. Therefore, in contrast to high income individuals, low and average income individuals are less likely to hold revolving credit card debt because they may be worried about the amount of such debt, which will add to their financial burden due to compounding interest rates (Kim and DeVaney, 2001). In addition, low- and average-income people would care about their personal credit over the long term. Therefore, to maintain a good level of personal credit (i.e., changeable utility from future resources into present resources), future-oriented individuals whose income is at low and average levels, are less likely to have delinquent credit card payments compared with their counterparts. Accordingly, we predict that income moderates the relationship between time perspectives and the probability of delinquent credit card debt and in turn moderates the indirect effect of morning orientation on delinquent credit card payments through the time perspective:

**Hypothesis 3**: Income moderates the relationship between time preference and delinquent credit card payments.

**Hypothesis 4**: The indirect effect of morning-types on delinquent credit card payments through the time perspective, is moderated by income, such that the indirect effect exists for those whose income is at low and average levels.

**Morning larks and owning equity (H5)**

The second goal of the present paper is to investigate the relationship between morning-types and the likelihood of owning hold stock. Prior studies have documented the determinants of stock market participation. They include wealth (Visser-Jorgensen, 2002), education (Bayer et al., 2009), background income risk (Guiso et al., 1996; Heaton and Lucas, 2000), physical health (Rosen and Wu, 2004), mental health (Bogan and Fertig, 2013), financial literacy (Grinblatt et al., 2011), trust (Guiso et al., 2008), and cultural and social interactions (Hong et al., 2004; Grinblatt and Keloharju, 2001). More recently, Rao et al. (2016) reported that happiness is positively associated with investments in stock, whereas Biss and Hasher (2012) reported that both younger and older people who are morning larks have higher levels of happiness. Therefore, we propose as follows:

**Hypothesis 5**: Morning-types are positively associated with investments in stock. In particular, compared with intermediate- and evening-types, morning larks are more likely to participate in the stock market.

**The mediating role of financial risk preference (H6)**

To provide a richer explanation of why morningness influences investments in stock, we use theories of financial risk preferences. On the one hand, previous research reported that morning larks are less
likely to engage in financial risk behaviour and are negatively associated with risk attitudes (Wang and Chartrand, 2015). These researchers argued that self-control is the underlying mechanism, as self-control is able to inhibit impulsivity, which contributes to risky behaviour. Morningness-types tend to be less impulsive. Guven and Hoxha (2015) supported this argument as well. Accordingly, it is reasonable to expect that morning larks have a lower level of financial risk preference compared with evening owls. On the other hand, another stream of literature advocated the opposite, such that happiness is positively associated with risk attitude. Anderson and Galinsky (2006) documented that optimism increases individuals’ risk preferences, as optimistic people’s cognitive appraisals engender high certainty and a higher probability of positive outcomes. Depressed-mood people are more risk averse compared with neutral and positive-mood individuals (Yuen and Lee, 2003). Although the prior literature has provided contradictory arguments regarding the relationship between positive moods and risk preference, given the evidence in the literature about the association between the morning chronotype and risk attitude, and that risk preference as a predictor of participation in the stock market (Dohmen et al., 2011), we propose the following hypothesis:

Hypothesis 6: Financial risk preference mediates the relationship between morning-types and stock market participation.

The moderating role of monthly income in a first-stage moderated mediation model (H7 and H8)

We have proposed that morningness influences the likelihood of investment in stock through financial risk preference, and we anticipate the strength of this mediating effect to vary according the level of income in the path from morningness to financial risk preference. Income is a determinant of individuals’ general risk attitude, and financial risk attitude (Dohmen et al., 2011). These researchers reported that wealthier people are more willing to take risk. Tanaka et al. (2010) also argued that income is associated with risk preference. Therefore, the effect of morningness on financial risk preference is stronger in the group of people who have average- and high-income levels. Accordingly, we propose as follows:

Hypothesis 7: Income moderates the relationship between morning-types and financial risk preference.

Hypothesis 8: The indirect effect of morning-types on investments in stock through financial risk preference is moderated by income, such that an indirect effect exist for those whose income is at average and high levels.

To summarize, we illustrate the conceptual models in Figure 1 and Figure 2.
3. Methods

3.1 Sampling and data validation

We gathered the data by using an Internet-mediated survey, which was considered the only financially affordable choice because the target population (experienced labour force in China) is large and geographically scattered (Edwards et al., 2009). This survey comprises four parts. The first part was a participation information sheet that describe the academic purpose and objective of this research, gave the consent choice to potential respondents, and clarified that the data would remain confidential. The second part included a number of questions regarding circadian rhythms. The third and fourth parts asked for demographic information, individual in risk and time preferences and specific financial behaviour (i.e., holding stock and having revolving credit card debt).
The present study distributed an online survey on Wjx (2017) (previously called Sojump), which is a well-known online panel service provider in China. Online panel data collection is different from traditional online data collection because it collects data from registered online panel registers who agree to respond questionnaires for monetary compensation (Johnson, 2016). Wjx has a large survey-oriented sample pool (more than 2.6 million) in different cities in Mainland China that possesses diverse demographic features. In particular, Wjx selectively invites volunteers and individuals in their registered sampling pool to fill out an online survey, based on its customers’ sampling frame. After validation, each respondent is given a monetary award. Hence, our sample should be deemed as a convenient sample (Hays et al., 2015). The survey was initially drafted in English and was subsequently translated to Chinese by the author that is natively speaking Chinese. Afterwards, another native Chinese speaker checked the consistency of the Chinese version survey (Chen et al., 2016).

The Ethics and Research Governance group at the authors’ institution approved this study. All subjects were given inform consent and they were willing to joining the survey.

Totally, Wjx distributed the survey to 4472 panelists who fit the eligibility criteria in their panel, and 582 full-time employees in China with 3 to 8 years of working experience completed the survey. Because we enabled a force response setting in the survey, there are no missing values. We also enabled attention checks to identify irresponsible participants, which helped to automatically discard 56 questionnaires. Therefore, in fact, we totally collected 526 observations. We further deleted 71 observations because these respondents did not use credit cards, which is one of the interests of the present study, ultimately resulting in 455 observations. Figure 3 is a bar chart that displays the number of respondents from different provinces. Figure 4 illustrates the distribution of respondents on a flat map of China generated in Excel 2016 and provides the population density of China in 2010 (Liu et al., 2015), in order to detecting whether our sample achieved adequate geographical disperse and representativeness. In general, our online sample roughly fits the geographical distribution of the general population.

In addition, we draw the reader’s attention to the four observations from overseas. We do not deny the possibility that these respondents had travelled to or temporarily visited overseas countries when they submitted the questionnaires.
Figure 3 reports the number of respondents from different provinces in China.

![The number of respondents from different provinces](image)

Note: This bar chart displays the number of observations by provinces. The x-axis lists the names of the provinces, while the y-axis lists the number of respondents from each province.

Internet-mediated surveys have the advantages of being a cheaper and faster way to collect data and reducing social desirability bias (Burkill et al., 2016; Kreuter et al., 2008). However, Couper (2017) reported that there are challenges for inferential studies using this mode for surveys, such as non-response bias (i.e., low response rate) and coverage bias (i.e., offline population concerns (Callegaro and DiSogra, 2008)). The response rate is broadly deemed to be an important sign of data quality (Biemer and Lyberg, 2003). Accordingly, in this paper, the response rate was 13.01% (582/4472), which is low and quite similar to likely response rate 11% mentioned by Saunders et al. (2012; pp. 421). Therefore, it raised concern about data quality (Couper, 2017; Meterko et al., 2015).

Figure 4 depicts the locations of the sample participants who live in in China (left) and the population density of China in 2010.

![Locations and population density](image)

Note: Each solid blue point represents the location of one respondent. From the perspective of geography, our samples are distributed randomly across the provinces of China. The diagram on the right displays the population density of China in 2010 (Liu et al., 2015).

Nevertheless, researchers should evaluate the merits of survey results and not depend solely on the response rate (Meterko et al., 2015), as a low response rate does not necessarily indicate non-response bias, although it raises suspicion. A study with a low response rate that examines relationships should not automatically be assumed to be problematic or less credible (Rindfuss et al., 2015). Potential non-
response bias derived from a low response rate is less of a concern in a relationship-oriented analysis than in a distributional analysis and non-response bias can indicate discrepancies in survey items (Rindfuss et al., 2015; Groves and Peytcheva, 2008; Smith, 2009). In the literature, there is empirical evidence supporting that the contention that there is little difference in the results between low-response rate surveys and high-response-rate surveys, such as Smith (2009), Visser et al. (1996), Curtin et al. (2000), Keeter et al. (2006). More recently, Holbrook et al. (2007) stated that low-response survey diminished demographic representativeness, but not that much.

Other concerns with using an online panel survey are coverage bias and self-selection bias. To quantitatively examine these types of bias and determine how our sample may be different from the target population, it is helpful to compare our sample data with the census data regarding Internet penetration, education, age and gender. First, the Chinese population as of 2017 is 1.4 billion (Worldometer, 2017), of which approximately 1 billion can access Internet (Statista, 2017). Therefore, Internet penetration in China now is approximately 71.4%. In other words, approximately 28.6% of the population are non-Internet user and are therefore not covered in the sample. Hence, the results would be possibly biased, as the findings might only represent 71.4% of the entire population. In addition, regarding the education level of the labour force, the median educational attainment in our sample is the undergraduate level, which is higher than shown in census data, as only 36.5% of the general population have experienced tertiary education (World Development Indicator, 2017). This is a disadvantage of an Internet-mediated survey, which tends to generate a sample with higher educational attainment than the census data (Paz et al., 2013). Therefore, we remain cautious and acknowledge these limitations of using an online panel survey in this paper. Nevertheless, age, income and the gender ratio of our sample quite closely match the labour force population in China. First, the proportion of working females in our sample is 62%, and one study reported that 56.7% of the workforce in China are females (Community Business, 2014). Second, as of 2017, China’s average per capita income was 8,480 US dollars (equivalent to 56,114 Yuan) (International Monetary Fund, 2017), which is quite close to the median category of monthly income in our sample of between 5,000 and 7,500 US dollars (equivalent to annual income 60,000 and 90,000 Yuan). Third, the average age of the labour force in China is 36 years old (China Human Capital Report, 2016), which is within the median group of our sample of between 30 and 44 years old.

3.2 Measures

**Chronotype.** The composite scale (CSM) (Smith et al., 1989) extracts 13 items from the Horne and Ostberg scale (Horne and Ostberg, 1976) and the Torsvall and Akerstedt scale (Torsvall and Åkerstedt, 1980). It is widely used to measure morningness-eveningness and has multiple language versions, including French (Caci et al., 1999), Spanish (Adan et al., 2005), German (Randler, 2008c), and Thai (Pornpitakpan, 1998). Specifically, nine items from Hornes and Osberg (Smith et al., 1989) have
Chinese versions in the literature (Gau et al., 1998; Li et al., 2011); and thus, we directly used these items in the questionnaire. However, four items are from the Torsvall and Akerstedt (1980) scale (their items 1, 4, 6, and 7), which have not been translated into Chinese in the literature. Therefore, we invited a Chinese native speaker who is proficient in both English and Chinese to translate these four items in parallel to ensure the validity and conceptual correspondence for the Chinese circumstance. The CSM scale ranges from 13 (extreme evening owl) to 65 (extreme morning larks). Furthermore, we tested the reliability of this measure in the Chinese version using Cronbach’s alpha (1951). Hinton et al. (2014) proposed four interval-based categories to assess the reliability of a summative scale (Likert, 1932), which consist of excellent reliability (0.90 and above), high reliability (0.70-0.90), moderate reliability (0.50-0.70), and low reliability (0.50 and below). The Cronbach’s alpha for the Chinese adaptation of the CSM was 0.879, indicating that it is highly reliable, and this value is very close to that of the original English version of the CSM (Smith et al., 1989; Cronbach’s alpha=0.87). Finally, we categorized the continuum of the CSM values into three chronotypes, following Smith et al. (1989). We have 60 observations of morning-types (44 and above), 384 observations of intermediate-types (23–43), and only six observations of evening-types (22 and less). The three chronotype samples in our study are not evenly distributed. In particular, our sample is represented by 13.18 percent, 84.62 percent and 2.20 percent following the morningness, intermediate and eveningness classification, which indicates the majority are intermediate type. By comparison, we note that our sample distribution is similar to those by Lau et al. (2017) and Wong et al. (2017) that also used CSM scale. The distribution of their sample according to morningness, intermediate and evening classification is 7.12 percent, 85.87 percent and 7.01 percent and 2.5 percent, 84.8 percent and 12.7 percent, respectively. Consequently, we address the difference in distribution by carrying out further tests using the adopted cut-off criteria proposed by Wong et al. (2012), which is eveningness, intermediate and morningness at 22 and below, 23–40 and 41 and above respectively. Our robustness test reveal that the results are similar to those in Appendix B with the exception that the circadian rhythm scale is replaced by the newly categorized morningness. All remaining results support the hypothesised relationships. Because of the very few observations of evening type, we re-categorized the sample to generate one binary variable, where one indicates morning-type while zero denotes non-morning-type.

**Time preference.** We use a combination of intertemporal behaviour to proxy time preference, as proposed by Finke and Huston (2013), who constructed a summative scale using eight items, each representing one behaviour, with outcomes at different time points. The reason is to choose this method is that Finke and Huston (2013) showed that this additive index is a strong predictor for measuring time discounting compared with traditional measurements in which respondents are asked to choose between receiving a small amount of money right now or a larger amount of money in the future. We also invited a native Chinese speaker who are proficient in both English and Chinese to translate these questions. Participants sequentially answered seven of eight questions about wearing a seatbelt when driving a car,
smoking, drinking wine, using nutrition labels when shopping for food, engaging in arduous physical exercise, unprotected sex behaviour, and choosing food for the purpose of maintaining diet. Nevertheless, the last question was dropped, which asked whether the respondent used drugs or any controlled substances. Because both the recreational and medical use of marijuana or cannabis are banned and severely enforced throughout China (Bi, 2012), this question was not appropriate. Respondents were asked to respond on a five-point Likert scale ranging from “never” to “always”. For positive behaviour, such as wearing the seatbelt when driving a car, we coded 1 for those who never wear the seatbelt and 5 for those who always wear it. In contrast, for negative behaviour, such as consuming wine, we coded 1 for those drink wine almost every day and 5 for those who never consume alcoholic drinks. Hence, this additive scale ranges from 7 to 35, where higher scores represent individuals who emphasize future goal attainment and delay gratification. The Cronbach’s alpha for this Chinese version time perspective scale was 0.573, indicating that it is moderately reliable.

**Risk preference.** We use one simple and behaviourally valid survey question to measure risk attitudes in a financial context, following Dohmen et al. (2011). Although economists question whether self-reported individual preference and traits are behaviourally meaningful due to incentive compatibility, Dohmen et al. (2011) reported that this measure maps onto actual monetary outcomes from lottery choice experiments (Holt and Laury, 2002; Eckel et al., 2008), which in turn give us confidence using this survey question to elicit risk attitudes. This question directly asks respondent to make a general assessment regarding their willingness to take financial risk: “How willing are you to take risks, in financial matters?” Participants rate their financial risk attitude from 0 to 10. More importantly, this measure is empirically valid in explaining individual differences in financial decision, such as investments in stock, in a large representative survey. We also translated this question into Chinese, as we distributed this survey in Mainland China.

**Financial behaviour.** We aim to investigate whether and how the circadian typologies may influence individual’s credit behaviour, such as delinquent credit card payments. We asked the respondents one simple question: “Please indicate below the option that best describes your payments on credit cards.” Six exclusive options are available (Mandell and Klein, 2009; Fernandes et al., 2014), including “I do not use credit cards for payments” (0), “Always pays off monthly” (1), “Generally pays off monthly” (2), “Occasionally pays off monthly” (3), “Seldom pays off, but tries to pay down” (4), and “Generally pays minimum each month” (5). We deleted the observations which selected “I do not use credit cards for payments” and then recoded zero for respondents providing the answer “Always pays off monthly” and one for the other answers. We also examine whether and how circadian rhythms affect individuals’ investment behaviour, such as willingness to participate in the stock market. We asked one simple question: “Have you ever invested in stock market?” Two options are provided. We scored one if respondents answer “Yes” and score zero if respondents answer “No”. These questions were translated into Chinese when distributing the surveys to the respondents.
**Control variables.** To reduce omitted variable bias when estimating the effect of morningness-eveningness on the preference constructs and in turn financial behaviour (i.e. revolving credit card debt and investments in stock), we included demographic information in the survey. Specifically, the survey included age, gender, marital status, education, and monthly income (Almenberg and Dreber, 2015; Meier and Sprenger, 2010; Van Rooij et al., 2011; Eckel and Grossman, 2008; Lawrance, 1991; Rosen et al., 2003; Borghans et al., 2009; Bucciol and Miniaci, 2011; Dittrich and Leipold, 2014). We measure age with a single question “What is your age?” Respondents were provided with three options, “18 to 29 years old”, “30 to 44 years old”, and “45 to 54 years old”, which are marked from 1 to 3. Male is dichotomously measured, where one indicates male and zero otherwise. Marital status is also a binary variable, where one indicates married and zero otherwise. Educational attainment is an ordinal variable that ranges from one to six, denoting “Lower than high school”, “High school”, “College”, “Bachelor’s degree”, “Master’s degree”, and “Doctoral degree”, respectively. The measurement of monthly income is a single question: “What is your monthly income?” Respondents were provided with six options, consisting of “Less than 3000”, “3000 to 5000”, “5000 to 7500”, “7500 to 10000”, “10000 to 20000”, and “More than 2000”, which are marked from 1 to 6, respectively. The units are RMB. We translated these questions into Chinese when distributing the surveys. To summarize, these variables are possibly exogenous with respect to individual preferences and financial behaviour and can therefore, which is used to help interpreting links in the regression estimates.

To view the original questions for these measurements, please see Appendix A.

### 3.3 Data description

Table 1 reports descriptive statistics of the measured variables. The distribution of respondents in the circadian typology groups was 60 in the morning type (13.19%) and 395 in the non-morning-type (86.81%). The distribution of time preference scores (skewness=-0.522; Kurtosis=4.043) and financial risk preferences (skewness=-0.857; Kurtosis=3.636) were both left-skewed; thus, the results associated with these measures must be treated carefully. A total of 65.7% and 34.1% of the respondents invest in the stock market and have the credit card debt, respectively. In addition, we have a relatively gender-balanced sample (177 men and 278 women).

The Pearson’s correlation matrix of the variables is shown in Table 2. The correlation analysis supported the majority of the proposed hypotheses. As expected, morning larks are prone to being future-oriented (r=0.262, p<0.01) and are less likely to have unpaid credit card debt (r=-0.157, p<0.01). Second, morning-oriented people are more risk taking (r=0.131, p<0.01) and in turn are more likely to invest in the stock market (r=0.303, p<0.01).
To test the level of collinearity, we calculated the variance inflation factors for the variables, and they are all smaller than 2, suggesting that the level of collinearity is not problematic (Neter et al., 2004). To further examine the relationships between the key variables of interest, we use the independent group t-test to examine mean difference on concerned variables between morning-types and non-morning-types. Specifically, morning-types scored higher on time perspective (M=27.150; SD=0.345) than non-morning-types (M=24.863; SD=0.145), t(453)=5.771, p<0.001, difference=2.29) and had a higher level of financial risk taking (M=8.217; SD=0.257, vs. M=7.471; SD=0.096, t(453)=2.816, p<0.001, difference=0.746).

### 3.4 Econometrics model

To test the direct effect of morningness on delinquent credit card payments (Hypothesis 1) and on investments in stock (Hypothesis 5), we use a logistic regression model, since delinquent credit card payments and investments in stock are dichotomously-measured dependent variables. Additionally, logistic regression also has a number of advantages. First, neither the dependent nor the independent variables have to be normally distributed. Similarly, logistic regression does not assume that the error terms have to be in normal distribution. More importantly, it does not assume that the relationships between the independent and dependent variables are linear.

We specify the following logistic models to test relationship between morning-type and delinquent credit card payments (Hypothesis 1):
**Table 2** Pearson’s correlation coefficients for key study variables.

</table>
Delinquent credit card payment<sub>i</sub> = β₀ + β₁Morningness + β₂Time preference + \sum_{k=5}^{K} β_k X_{ik} + \epsilon_i,  

where X_{ik} is the set of control variables of individual i, including age, male, marital status, education, and monthly income. \epsilon_i is the error term.

The model specification to examine the link between morning-type and stock ownership is as follows (Hypothesis 5):

Owning stock<sub>i</sub> = β₀ + β₁Morningness + β₂Financial risk preference + \sum_{k=5}^{K} β_k X_{ik} + \epsilon_i,  

where X_{ik} is a vector of control variables of individual i, including age, male, marital status, education, and monthly income. \epsilon_i is the error term.

To test the moderating role of income on the link between time preference and delinquent credit card debt (Hypothesis 3), we use a logistic regression model with an interaction item (Time preference × Monthly income), as delinquent credit card debt is a dichotomous variable. The model specification is:

Delinquent credit card debt<sub>i</sub> = β₀ + β₁Time preference + β₂Time preference × Monthly income + β₃Monthly income + \sum_{k=4}^{K} β_k X_{ik} + \epsilon_i,  

where X_{ik} is a vector of control variables of individual i, including age, male, marital status, and education. \epsilon_i is the error term.

To test the moderating role of income on the link between morning type and financial risk preference (Hypothesis 7), we use an OLS regression model with an interaction item (Morning type × Monthly income). The model specification is:

Financial risk preference<sub>i</sub> = β₀ + β₁Morning type + β₂Morning type × Monthly income + β₃Monthly income + \sum_{k=4}^{K} β_k X_{ik} + \epsilon_i,  

where X_{ik} is a vector of control variables of individual i, including age, male, marital status, and education. \epsilon_i is the error term.

To test above hypotheses, we used Stata 15.1.

Next, we used path analysis to test whether time perspective mediates the relationship between morning-type and delinquent credit card payments (Hypothesis 2) and whether financial risk attitude mediates the link between morning-type and investments in stock (Hypothesis 6). To test these mediation models, we used the PROCESS 2.16.3 macro (Hayes, 2011) in SPSS 24.0 and conducted bootstrapping with 5,000 resampling to verify the statistical significance. Furthermore, we also used path analysis with in the PROCSS macro to investigate the moderating role of income on the indirect effect between morningness and delinquent credit card payments through time preference, on the path from time preference to delinquent credit card payments (Hypothesis 4). Similarly, we applied this method to examine whether income affects the indirect effect of morningness on stock ownership through financial risk preference on path from morningness to financial risk preference (Hypothesis 8).
4. Results

4.1 Direct effect of morning chronotype on the likelihood of having revolving credit card debt (H1)

Table 3 reports the average marginal effect of morningness on delinquent credit card payments based on the logistic regression. The independent variable is morningness, indicating the morning type of circadian chronotypes. The results indicate that morning types are negatively associated with delinquent credit card payments. In other words, compared with the other chronotypes, the percentage of having delinquent credit card payments for morningness people is 22.3% lower. Although we control for age, male, marital status, education, monthly-income, and time preference, only time preference is significant in predicting the variance of delinquent credit card payment. In summary, results indicate that morning types attenuate revolving credit card payments, which are in support of hypothesis 1.

4.2 The mediating role of time perspective (H2)

First, we use OLS regression to investigate the relationship between morningness and time preference. Second, a logistic regression is performed to examine the relationship between time preference and delinquent credit card payments. Consequently, we are able to test whether time preference mediates the link between morningness and delinquent credit card payments (Hypothesis 3). Table 4 reports the results of this mediation model. The results indicate that the morning chronotype is positively associated with time preference (path a: coefficient is 2.136, SE=0.375, t=5.701) and time preference is negatively associated with delinquent credit card payments (path b: coefficient is -0.087, SE=0.037, z=-2.367). Since a-path and b-path are both significant, which indicates that there is a mediation effect. To further test the significance of this mediation effect (indirect effect a*b), we use the bootstrapping method with bias-corrected confidence estimates (Preacher and Hayes, 2008). Subsequently, the 95% confidence interval of the indirect effect is taken with 5,000 bootstraps resamples (Preacher and Hayes, 2008). If the confidence interval of the estimator does not contain 0, it indicates that the indirect effect is significantly different from zero. The results of the bootstrap test show that time preference mediates the link between morningness and the delinquent credit card payments (indirect effect=a*b=-0.186, SE=0.090, 95% CI =from -0.381 to -0.029). Moreover, when adding time preference, the relationship between the morning chronotype and delinquent credit card payments is still significant (path c’: coefficient is -1.045, SE=0.386, Z=-2.704). This results means that time preference is a partial mediator. To summarize, the results are in support of hypothesis 2. In other words, we find that time preference is one channel through which morningness negatively influences the likelihood of delinquent credit card payments.
4.3 The moderating role of income on the indirect effect of morningness on delinquent credit card payments (H3 and H4)

Table 5 summarizes the statistical results of the moderation model that investigates the moderating effect of monthly income on the relationship between time preference and delinquent credit card payments. The dependent variable is delinquent credit card payments. The independent variable is time preference, and the moderator is monthly income. We grand-mean-center the moderator (Monthly income) and the independent variable (Time preference) according to the approach proposed by Aiken et al. (1999). In particular, after the effects of the control variables and the main effects of time preference are accounted, we find that the coefficient of the cross product between monthly income and time preference is $0.062$, $t=2.228$, $p=0.026$, yielding a significant interaction effect in relation to delinquent credit card payments. The results support Hypothesis 3.

To explore the indirect relationship between morningness and delinquent credit card payments through time preference would be conditional on the moderator variable of monthly income for the path from time preference to delinquent credit card payments, we use the bootstrap methods proposed by Hayes (2013) to test this hypothesized second-stage moderated mediation model (Hypothesis 4). The first step is to examine the interactive effect of time preference and monthly income on delinquent credit card payments. The results suggest that the interaction term between monthly income and time preference is significant ($b=0.062$, $p<0.05$). Table 6 displays the details. The second step is to investigate the conditional indirect effects at 1 standard deviation above (high monthly income), at 0 standard deviation from (average monthly income), and at 1 standard deviation below the mean of the moderator (low monthly income). Table 6 reports the details of the moderated mediation model test.

</tbody>
</table>

Note: Unstandardized regression coefficients are reported; bootstrap sample size=5,000. CI=confidence interval; LL=lower limit; UL= upper limit. * indicates p<0.1, ** indicates p<.05, and *** indicates p<0.01.

In particular, for low monthly income, the moderated mediation model is significant (indirect effect= -0.368, SE=0.138, 95% CI = [-0.666, -0.139]). Therefore, morning-type people with low monthly income have less likelihood of delinquent credit card payments by 0.368. Similarly, for average monthly income, the moderated mediation model is also significant (indirect effect=0.224, SE=0.094, 95% CI = [-0.430, -0.062]). Hence, morning-type people with average monthly income have a propensity for decreasing the likelihood of delinquent credit card payment by 0.224. However, for high monthly income, the moderated mediation model is not significant (indirect effect=-0.079, SE=0.097, 95% CI = [-0.283, 0.104]). The index of moderated mediation (Hayes, 2015) quantifies this conditional indirect effect (b=0.131, SE=0.067, 95% CI= [0.012, 0.270]). Together, the results indicate that morningness is
more likely to influence delinquent credit card payment behaviour through time preference when income is at low and average levels.

To summarize, there findings above indicate that the morning chronotype influences delinquent credit card payments through time preference, and that the indirect effects change according to different levels of monthly income.

4.4 The direct effect of morningness on the likelihood of investments in stock (H5)

Table 7 reports the average marginal effect of morningness on stock market participation using a logistic regression. The independent variable is morningness, indicating the morning type of circadian chronotypes. The results indicate that morning type is not positively associated with stock market participation (average marginal effect of morningness is 0.105, SE=0.063, z-statistics=1.66, p=0.098).

In other words, comparing with other chronotypes, the percentage of owning stock for morningness people is not significant from zero. In summary, the results do not support Hypothesis 5.

Note: The dependent variable is stock market participation. This table reports the average marginal effect based on logistic regression examining the effect of morningness on the stock market participation. The sample is China residents who have been working for 3 to 8 years, randomly sampled with the online survey. *, **, and *** indicate significance at 10% level (2-sided), 5% level, and 1% level, respectively.

4.5 The mediating role of financial risk preference (H6)

First, an OLS regression is used to investigate the relationship between morningness and financial risk preference. Second, a logistic regression is conducted to examine the relationship between financial risk preference and stock market participation. Consequently, we are able to test whether financial risk preference mediates the link between morningness and stock market participation (Hypothesis 6). Table
8 reports the results of this mediation model. The results indicate that the morning chronotype is positively associated with financial risk preference (path a: coefficient is 0.745, SE=0.277, t=2.688). This finding contradicts that of Wang and Chartrand (2015). In addition, financial risk tolerance is positively associated with stock market participation (path b: coefficient is 0.293, SE=0.059, z=4.934). Since a-path and b-path are significant, the results indicate that there is a mediation effect. To further test the significance of this mediation effect (indirect effect a*b), we use the bootstrapping method with bias-corrected confidence estimates (Preacher and Hayes, 2008). Next, the 95% confidence interval of the indirect effect is taken with 5,000 bootstraps resamples (Preacher and Hayes, 2008). If the confidence interval of the estimator does not contain 0, it shows that the indirect effect is significantly different from zero. The results of the bootstrap test showed that financial risk preference mediates the link between morningness and stock market participation (indirect effect=a*b=0.219, SE=0.095, 95% CI =from 0.067 to 0.435). Moreover, when adding financial risk preference, the relationship between the morning chronotype and stock market participation turns becomes non-significant (path c’: coefficient is 0.543, SE=0.351, Z=1.551). This result means that financial risk preference is a full mediator. To summarize, the results are in support of Hypothesis 6. In other words, financial risk preference is one channel through which morningness positively influences the likelihood of stock market participation.

4.6 The moderating role of income on the indirect effect of morningness on stock market participation (H7 and H8)

Table 9 summarizes the statistical results of the moderation model that investigates the moderating effect of monthly income on the relationship between morningness and financial risk preference. The dependent variable is financial risk preference. The independent variable is morningness, and the moderator is monthly income. We grand-mean-center the moderator (Monthly income) and the independent variable (Morningness) according to the approach proposed by Aiken et al. (1999). In particular, after the effects of the control variables and the main effects of time preference are accounted, we find that the coefficient of cross product between monthly income and morningness is 0.209, SE=0.286, t=0.73, p=0.463, indicating that there is no significant interaction effect in relation to stock market participation. The results do not support Hypothesis 7.

Note: The dependent variable is financial risk preference. Monthly income is the moderator. This table reports the coefficients from the OLS regression examining the moderating effect of monthly income on the relationship between morningness and financial risk preference. The sample is China residents who have been working for 3 to 8 years, randomly sampled with the online survey. *, **, and *** indicate significances at the 10% level (2-sided), 5% level, and 1% level, respectively.

To explore whether the indirect relationship between morningness and stock market participation through financial risk preference would be conditional on the moderator variable of monthly income for the path from morningness to financial risk preference, we use the bootstrap methods proposed by Hayes (2013) to test this hypothesized first-stage moderated mediation model (Hypothesis 8). The first step is to examine the interactive effect of morningness and monthly income on financial risk preference. The results suggest that the interaction term between morningness and monthly income is not significant (b=0.210, SE=0.305, t=0.688, p>0.05). The second step is to investigate the conditional indirect effects at 1 standard deviation above (high monthly income), at 0 standard deviation from (average monthly income), and at 1 standard deviation below the mean of the moderator (low monthly income). Table 10 reports the details of the moderated mediation model test.

Note: Unstandardized regression coefficients are reported; bootstrap sample size=5,000. CI=confidence interval; LL=lower limit; UL= upper limit. * indicates p<0.1, ** indicates p<.05, and *** indicates p<0.01.

Since the interaction between morningness and monthly income is not significant and the index of moderated mediation model is not significant (Index=0.064, SE=0.095, 95% CI=[-0.107, 0.279]), the results indicate that there is no conditional indirect effect between morningness and stock market participation through financial risk preference.

To summarize, the findings above indicate that morning chronotype influences stock market participation fully through financial risk preference and that this indirect effects do not vary at different levels of monthly income.

4.7 Robustness check

We changed the dichotomously measured morningness in the benchmark analysis to a continuum scale because Chelminski et al. (1997) proposed the idea of using continuum scale of morningness-eveningness, which may provide richer information regarding the hypothesized relationships. We also used a different single question also proposed by Dohmen et al. (2011) to measure risk preference, which can generate an all-around factor to predict risky behaviour. In addition, we added both risk and
time preference measures in all settings of the regression and path analyses, as risk and time are intertwined. It would be problematic to isolate risk attitude, when studying time preference (Andreoni and Sprenger, 2012), because uncontrolled risk preference can create present-biased choices or behaviour. By changing the measures of the key variables of interests and increasing bootstrap sample size from 5,000 to 50,000, we intend to verify the robustness of our results.

The analysis first shows that circadian rhythm is negatively associated delinquent credit debt payments, and time perspective partially mediates this relationship. In addition, income moderates this indirect effect on the path from time preference to delinquent credit debt payments. Second, risk preference still fully mediates the positive association between circadian rhythm and the likelihood of participating in the stock market. Consequently, the results are still robust after changing the measurements of key variables, which enhances the empirical evidence supporting the hypothesized relationships. For brevity purposes, we report the details of robustness check in Appendix B.

5 Discussion

The first goal of the current study was to explore the effects of circadian rhythm on financial behaviour, including revolving credit card payments and stock market participation as well as the possible mechanisms (i.e., channels) through which these effects take place. In particular, we aim to get a better understanding of the links between 1) circadian rhythm, time preference, and delinquent credit card payments as well as the relationships between 2) circadian rhythm, financial risk preference, and stock market participation. In fact, we investigated that how morningness is related to the likelihood of delinquent credit card payments, and whether time preference is one channel through which morningness indirectly affects the likelihood of delinquent credit card payment. In addition, we test how income moderates the mediating relationship between morningness, time preference, and delinquent credit card payments. Partially as expected, the survey results empirically demonstrate that morningness is negatively associated with the likelihood of delinquent credit card payments. Time preference is one of the channels through which that morningness influences the likelihood of incomplete credit card debt. Moreover, this indirect relationship is identified to be significant if and only if individuals have median or high level of monthly income.

The second goal of this paper was to examine the effects of circadian rhythm on stock market participation and explore the plausible channels through which these effects occur. Specifically, we examine how morningness is associated with the likelihood of stock market participation, and whether financial risk preference is one channel through which morningness indirectly influence the likelihood of stock market participation. Additionally, we test whether income moderates the mediating relationship between morningness, financial risk preference, and delinquent credit card debt. The results confirm that morningness only influences the likelihood of participating in the stock market through financial risk preference. An additional finding is that the results indicate that morningness is positively
associated with financial risk preference, which contradicts to the previous studies that reported morningness is inversely related to risk taking (Wang and Chartrand, 2015; Killgore, 2007; Maestripieri, 2014). Finally, neither morningness is directly associated with stock market participation nor income moderates the indirect relationship between morningness, financial risk preference, and participation in the stock market.

These findings have some important theoretical and practical implications.

5.1 Theoretical implications

In general, we extend the literature by adding the knowledge that circadian typologies can influence financial behaviour through individual economic differences (i.e., time preference and financial risk preference), and we provide an informative picture regarding the relationships between them based on inferential statistics.

We contribute to this stream of literature by recognizing that morning-type people can inhibit the probability of delinquent credit cards and time preference represents one of the channels through which this occurs. The research expands the present understanding of the functional effect of morningness-eveningness (Piffer et al., 2014) by theoretically and empirically suggesting the relationship between morningness and the likelihood of delinquent credit card payments. We propose and find at direct negative association between morningness and delinquent credit card payment, which makes it clear that the morning chronotype significantly suppresses the likelihood of revolving credit card debt. One possible mechanism for this association is self-control because morningness prompts individuals to be more self-regulated (Milfont and Schwarzenthal, 2014), which is negatively associated with non-payment of credit cards and the financial burdens of debt (Gathergood, 2012). Another possible mechanism for this link could be through a character inventory. Morning larks are more prone to being persistent (Randler and Saliger, 2012), conscientious (Randler, 2008a), and proactive (Cinan and Doğan, 2013) compared with evening owls. In particular, proactive people tend to examine, expect, and diminish the effects of potential problems in the future, avoiding them as much as possible (Aspinwall et al, 2002; Aspinwall et al., 2005). As a result, these people are more likely to avoid delinquent credit card debt. We also hypothesize and the results reveal that time preference partially mediates the relationship between morningness and delinquent credit card payments, thus replicating the association between morning chronotype and time perspective (Cinan and Doğan, 2013; Nowack and van der Meer, 2013), and expanding upon the initial work by using a Chinese sample. Morning larks appear to focus on future target attainment and suspend gratification (Milfont and Schwarzenthal, 2014). The study also extends the knowledge regarding the effect of morning-type on various behaviour that were mainly in the health and education fields (Piffer et al., 2014; Fleig and Randler, 2009; Nakade et al., 2009; Goldstein et al., 2007; Wittmann et al., 2010; Susman et al., 2007) to the financial field. An additional highlight is that the mediating role of time preference in the morningness-delinquent credit card
payment relationship goes beyond the effects of the demographic predictors that we control for in the analyses. Furthermore, by integrating insights from theories on time preference and credit card borrowing (Meier and Sprenger, 2010; Laibson, 1997; Fehr, 2002; Heidhues and Koszegi, 2010), and from theories on income and credit card debt (Calem and Mester, 1995), we propose and investigate how income moderates the mediating role of time preference on the morningness-delinquent credit card payments relationship. The findings show that time preference induced by a morning-oriented rhythm result in less likelihood of revolving credit card debt at mean and low levels of income. Specifically, the possible reason for the results regarding users of credit cards with low and mean levels of income is that they are concerned about the level of their financial debt, given the compounding rate of credit card debt. Because their financial situation is vulnerable to high interest rates, which will increase based on the amount of debt (Kim and DeVaney, 2001). Another concern of people with low and mean levels of income may be their personal credit over the long term. Given the evidence that income is positively associated with credit card balances at average and low levels of income (Calem and Mester, 1995), an increase in income for these groups of people may result in higher credit-card debt. Consequently, to maintain the utility of personal credit, future-oriented people with low and average levels of income will try their best to avoid any default-related behaviour. However, individuals with high level of income appear to be much less likely to be in a weak position such that their financial situation would be profoundly harmed due to unpaid credit card debt. For that reason, for this group of people, time preference is not a mediator for the likelihood of delinquent credit card payments.

Another important contribution of this study is to identify that circadian rhythms can exert influence on the probability of owning equity through financial risk preference. We advance the current understanding of the effect of morningness on risk behaviour related to investment matters by empirically investigates whether and how morningness affect financial risk taking and in turn influences stock market participation. We also offer possible explanations from multiple perspectives for why morning larks are prone to more risk taking, which can lead to the sequential outcome of owning equity. First, contrary to expectations (Wang and Chartrand, 2015), we find that morningness people are more likely to engage in financial risk taking. Since genetic factors (Hur, 2007) can explain a large amount of the variance of circadian typologies, and biological and physiological factors (Buschens et al., 2010; Roeser, 2012) are significant predictors of them, we are able to provide a plausible explanation. In the literature, Kandasamy et al. (2014) argued that acute cortisol lift-up is associated with increased physical arousal (Dallman and Bhatnagar, 2010), enhanced memory recall (Lupien et al., 2002), higher frequency of interaction with dopaminergic paths in the brain, promoted learning, induced behaviour, and sensation seeking. In addition, Cueva et al. (2015) clarified that cortisol and testosterone lead to increased financial risk preference. Therefore, the possible channel could be cortisol. Empirical research has suggested that the mean cortisol level of morning-type people is larger than the mean cortisol level of evening-type ones (Bailey and Heitkemper, 1991). Compared with evening owls, morning larks may have a higher level of cortisol in their first hour after waking (Kudielska et al., 2006). In addition,
morningness people have moderately greater cortisol concentrations after waking than eveningness individuals (Griefahn and Robens, 2008; Randle and Schaal, 2010). Because cortisol tends to directly increase risk taking, it could shed light on the positive association between morning-types and financial risk preference. Another possible channel could be testosterone, which could induce people to be more optimistic about risk regarding price changes in the financial market (Cueva et al., 2015), although Randler et al. (2012) at the first place put forward that testosterone is positively associated with evening-types in young adults between 20 and 30 years of age. Given this contrasting evidence, we do not deny that testosterone may also contribute to the higher level of risk taking among morning-oriented people, as our sample is quite heterogeneous from a demographic perspective. For example, our sample spans a larger age range (18 to 44 years old) and is a mixed gender sample rather than only males. A possible third channel is a happy mood. On the one hand, compared with evening owls, morning larks have higher levels of positive mood in both the young and old age groups, which make them happier (Yuen and Lee, 2003). When evening owls force themselves to get up early and produce in the daytime, it leads to some extent of sleep loss and emotional stress and in turn they are less happy. On the other hand, being happy is positively associated with a greater level of financial risk taking (Grable and Roszkowski, 2008). Positive emotional states, such as excitement and happiness, prompt individuals to take risks and to have more confidence in their abilities when making financial decisions (Kuhnen and Knutson, 2011). Second, with regard to the finding that financial risk preference fully mediates the relationship between morning-type people and owning equity as a behavioural consequence, it is straightforward to argue that financial risk preference is a unique channel. Empirical research in the risk attitude domain suggests that risk tolerance is positively associated with risky behaviour, including holding equity, which might be useful in many applications with a variety of different datasets (Barsky et al., 1997). Risk attitudes can explain the variance in risky behaviour, and the willingness to take risks in financial matters predicts the probability of owning stock much better than risk predictors do in other contexts (Dohmen et al., 2011). By integrating the evidence from the literature described above, we articulate the importance of the financial-risk taking process mechanism that is intrinsically embedded in the connection between morning-types and the probability of owning stock.

Empirical studies in the behavioural finance domain has focused on investigating the antecedents and outcomes of interest, in this case in terms of investment behaviour. Morningness-eveningness denotes biological rhythms, which is a temporality of humanity that cannot be backward, but only as an elemental level (Stolarski et al., 2013). We contribute by linking circadian rhythms with risk preference and time preference. Apprehending individuals’ decision-making both under risk and over time represent two fundamental domains of economic analysis (Tanaka et al., 2010) and policy design (Charness et al., 2013). However, they are distinctive conceptions (Andreoni and Sprenger, 2012; Kahneman and Tversky, 1979). Prospect theory (Kahneman and Tversky, 1979) takes risk attitude as a free parameter, while Zimbardo and Boyd (1999) defined time preference as a temporal category. It is therefore of benefit to explore their process mechanisms. Although cross-sectional research based on
regressions have limitation to clarify causality (Levin, 2006), we still have provided some reasonable explanation regarding the path from the circadian typologies to risk and time preferences in the above two paragraphs. Furthermore, we extend the empirical literature by identifying the mediating mechanism of risk and time preference between circadian rhythms and financial behaviour and the moderation mechanism of income in the indirect relationship between morningness and delinquent credit card payments through time preference. As such, we add fine-grained knowledge about whether, how and when circadian rhythms influence financial behaviour in a sequential process.

5.2 Practical implications

Given the evidence that morning larks are less likely to have revolving credit balances compared with evening owls. Morningness is indirectly and positively associated with the likelihood of participation in the stock market. From a financial perspective, evening-types do not seem to be in an advantageous position. Because in the short term, having delinquent credit card debt lead to higher interest rates, financial penalties, and higher outstanding balances (Elliehausen et al., 2007), and in the long-term, such behaviour harms financial well-being. In addition, non-participation in the stock market over the long term is costly because the stock premium is more likely to accumulate long-term benefits in personal savings, which in turn produce personal well-being. Therefore, we have following practical implication. For individuals, evening-oriented people should prevent from adopting poor loan payment habits in order to avoid unpaid credit debt, and they should pay loans back on time. In addition, empirical evidence indicates that evening owls may shift their sleep-wake time schedule to be closer to morning larks. Although the circadian chronotypes are time stable, this does not mean this characteristic is unchangeable. As a result, we anticipate that evening owls could have longer daytime to process information and deal with things, and become more proactive, more conscientious, as well as improve their mood, which may contribute to a higher likelihood of participation in the stock market. In addition, financial institutions can assess the chronotypes of customers as predictors of their behaviour. For example, financial institutions could remind evening-oriented customers about the due dates of their loan payment slightly more often but still in a soft manner, such as through email or app notifications. Furthermore, financial organizations could recommend customized portfolio according to customer’ circadian type. For example, financial risk involved with the suggested financial products for morning larks could be slightly higher than those proposed for evening owls.

6 Conclusion

In summary, to further understanding of the influence of circadian rhythms on specific financial behaviour (e.g., delinquent credit card payments and stock market participation), we integrated and examined the role of time perspective and risk preference in a sequential process. we conducted
regressions and path analysis based on an online survey sample representing the group of people who have been working for three to eight years in China. The findings show that compared to evening-type and neither-type individuals, morning larks are much less likely to have revolving credit card debt and one of the channels is the individual’s time perspective. However, time preference only partially mediates the relationship between morning chronotype and the probability of having revolving credit card debt when individual’ income level is at average and low, for the path from time preference to delinquent credit card payments.

Some limitations of this paper warrant mention. First, the sample included workers who have been working for 3 to 8 years and consequently, future studies could benefit from using a wider age spectrum. Second, the use of other measures of circadian rhythm, such as rMEQ (Carciofo et al., 2012) and MESSi (Randler et al., 2016) could potentially overcome the issue of unevenly distributed chronotypes in our Chinese samples. Third, it would be interesting to examine cultural and environmental differences with respect to our results and findings, such as in an individualism-oriented country and using culturally modified cut-off criteria of chronotypes proposed by Kerkhof (1985) and Caci et al. (2005) in future studies.

The present study helps to clarify the underlying mechanism and the condition in the link between circadian typologies and revolving credit card debt. Another novel finding is that risk preference fully mediates the relationship between morningness and the probability of owning equity. Therefore, the current study is also helpful to elucidate the unique channel and mechanism through which being morning-oriented exerts an influence on stock market participation. Furthermore, the results could be a valuable tool for financial professionals who could consider circadian rhythms when developing and introducing financial products or financial services to morning-type, intermediate-type, and evening-type populations. Future research could extend by studying the relationship between chronotypes, preference constructs, and financial behaviour by adding sampling frames, such as including aging cohorts, general populations in other countries. In addition, longitudinal studies are particularly of use to validate the proposed relationships. A further step could be to verify causal relationships among these variables by implementing behavioural experiments.

Appendix A

The questionnaire of this paper
Research Title: Chronotype, risk and time preference, and financial behaviours

Participant information sheet (English version of questionnaire)
ERGO-number 26671
Please read this information carefully before deciding to take part in this research.

What is the research about?
This research is going to investigate how circadian typology (morningness or eveningness) affect financial behaviour, such as incomplete credit card payment and stock market participation. Morningness refer to ones who are mentally and physically active during the morning hours while eveningness are ones who are more alert at night. We expect risk preference and time preference are able to bridge circadian typology and financial behaviour.

What will happen to me if I take part?
Participation will fill one questionnaire. It may take you 10 to 15 minutes to complete, including approximately 28 questions. Please make sure that you have sufficient time to finish if you are willing to joining. Your participation is very important because you will be profoundly contributing to this research.

Screening and eligibility?
If you have been working for 3 to 8 years and your age is +18 years old, you are eligible to take part in the research.

Will my participation be confidential and in safety?
There will be no risk in taking this survey. Your answers and personal information will be confidential. Your name and contact details will not be shown as it is not required to provide your name. Only the aggregate statistical data will be presented in this research, in terms of a paper in the future. Data and results will be stored properly according to the Data Protection Act and saved in a locked cabinet or encrypted file in a password-protected computer.

What happens if you change your mind?
You may withdraw your consent and participating in the study at any time. You will not be penalized for this.

Participants may wish to contact:
The researcher, Di Wang (dw2n13@soton.ac.uk).

☒ Yes, I am willing to join this survey.
☒ No, I do not want to join

Circadian Preference (Morningness or Eveningness)
Please check the response for each item that best describes you.
1.1. Considering only your own "feeling best" rhythm, at what time would you get up if you were entirely free to plan your day?
   5:00-6:30 a.m. (5)
   6:30-7:45 a.m. (4)
   7:45-9:45 a.m. (3)
   9:45-11:00 a.m. (2)
   11:00 a.m.- 12:00 (noon) (1)
1.2. Considering your only "feeling best" rhythm, at what time would you go to bed if you were entirely free to plan your evening?
   - 8:00-9:00 p.m. (5)
   - 9:00-10:15 p.m. (4)
   - 10:15 p.m.-12:30 a.m. (3)
   - 12:30-1:45 a.m. (2)
   - 1:45-3:00 a.m. (1)

1.3. Assuming normal circumstances, how easy do you find getting up in the morning? (Check one.)
   - Not at all easy (1)
   - Slightly easy (2)
   - Fairly easy (3)
   - Very easy (4)

1.4. How alert do you feel during the first half hour after having awakened in the morning? (Check one.)
   - Not at all alert (1)
   - Slightly alert (2)
   - Fairly alert (3)
   - Very alert (4)

1.5. During the first half hour after having awakened in the morning. How tired do you feel? (Check one.)
   - Very tired (1)
   - Fairly tired (2)
   - Fairly refreshed (3)
   - Very refreshed (4)

1.6. You have decided to engage in some physical exercise. A friend suggests that you do this one hour twice a week and the best time for him is 7:00-8:00 a.m. Bearing in mind nothing else but your own "feeling best" rhythm, how do you think you would perform?
   - Would be in good form (4)
   - Would be in reasonable form (3)
   - Would find it difficult (2)
   - Would find it very difficult (1)

1.7. At what time in the evening do you feel tired and, as a result, in need of sleep?
   - 8:00-9:00 p.m. (5)
   - 9:00-10:15 p.m. (4)
   - 10:15 p.m.-12:30 a.m. (3)
   - 12:30-1:45 a.m. (2)
   - 1:45-3:00 a.m. (1)

1.8. You wish to be at your peak performance for a test which you know is going to be mentally exhausting and lasting for two hours. You are entirely free to plan your day, and considering only your own "feeling best" rhythm, which one of the four testing times would you choose?
   - 8:00-10:00 a.m. (4)
   - 11:00 a.m.-1:00 p.m. (3)
   - 3:00-5:00 p.m. (2)
   - 7:00-9:00 p.m. (1)
1.9. One hears about "morning" and "evening" types of people. Which ONE of these types do you consider yourself to be?
   - Definitely a morning type (4)
   - More a morning than an evening type (3)
   - More an evening than a morning type (2)
   - Definitely an evening type (1)

1.10. When would you prefer to rise (provided you have a full day's work--8 hours) if you were totally free to arrange your time?
   - Before 6:30 a.m. (4)
   - 6:30-7:30 a.m. (3)
   - 7:30-8:30 a.m. (2)
   - 8:30 a.m. or later (1)

1.11. If you always had to rise at 6:00 a.m., what do you think it would be like?
   - Very difficult and unpleasant (1)
   - Rather difficult and unpleasant (2)
   - A little unpleasant but no great problem (3)
   - Easy and not unpleasant (4)

1.12. How long a time does it usually take before you "recover your senses" in the morning after rising from a night's sleep?
   - 0-10 minutes (4)
   - 11-20 minutes (3)
   - 21-40 minutes (2)
   - More than 40 minutes (1)

1.13. Please indicate to what extent you are a morning or evening active individual
   - Pronounced morning active (morning alert and evening tired) (4)
   - To some extent, morning active (3)
   - To some extent, evening active (2)
   - Pronounced evening active (morning tired and evening alert) (1)

Demographic information

2.1 What is your age?
   - 18-29 (1)
   - 30-44 (2)
   - 45-54 (3)

2.2 What is your gender?
   - Female (0)
   - Male (1)

2.3 Marital status:
   - Others (0)
   - Married (1)

2.4 Highest Level of Education Attained
   - Less than High School (1)
   - High school graduate (2)
   - Some college (3)
   - Bachelor degree (4)
2.5 What is your monthly income in Chinese RMB?
- Less than RMB3,000 (1)
- RMB3,000 to RMB5,000 (2)
- RMB5,000 to RMB7,500 (3)
- RMB7,500 to RMB10,000 (4)
- RMB10,000 to RMB20,000 (5)
- More than RMB20,000 (6)

2.6 Generally speaking, would you say that most people can be trusted, or that you cannot be too careful in dealing with people?
- Strongly disagree (1)
- Disagree (2)
- Somewhat disagree (3)
- Neither agree nor disagree (4)
- Somewhat agree (5)
- Agree (6)
- Strongly agree (7)

2.7 Have you invested in the stock market?
- No (0)
- Yes (1)

2.8 How do you see yourself? Are you generally a person who is fully prepared to take risks or do you try to avoid taking risks? Please tick a choice on the scale, where the value 0 means 'not at all willing to take risks', and the value 10 means 'very willing to take risks'

0 1 2 3 4 5 6 7 8 9 10

2.9 How do you see yourself? Are you generally a person who is fully prepared to take financial risks or do you try to avoid taking financial risks? Please tick a choice on the scale, where the value 0 means 'not at all willing to take financial risks', and the value 10 means 'very willing to take financial risks'

0 1 2 3 4 5 6
2.10 Please indicate below the option that best describes your payments on credit cards.
I do not use credit cards for payments (0)
Always pays off monthly (1)
Generally pays off monthly (2)
Occasionally pays off monthly (3)
Seldom pays off, but tries to pay down (4)
Generally pays minimum each month (5)

Time preference
3.1 When you are driving a car, how likely is it that you are wearing your seatbelt?
Never (1)
Sometimes (2)
About half the time (3)
Most of the time (4)
Always (5)

3.2 How often do you smoke cigarettes?
Never (5)
Sometimes (4)
About half the time (3)
Most of the time (2)
Always (1)

3.3 How often do you consume alcoholic beverages?
Never (5)
Sometimes (4)
About half the time (3)
Most of the time (2)
Always (1)

3.4 How often do you use nutrition labels to select the foods you buy?
Never (1)
Sometimes (2)
About half the time (3)
Most of the time (4)
Always (5)

3.5 How often do you engage in strenuous physical exercise?
Never (1)
Sometimes (2)
About half the time (3)
Most of the time (4)
Always (5)

3.6 How often have you engaged in unprotected sex during the last year?
Never (5)
3.7 How often do you choose foods for the purpose of creating a diet that will reduce your chances of having a diet-related illness in the future?

- Never (1)
- Sometimes (2)
- About half the time (3)
- Most of the time (4)
- Always (5)
Appendix B

Robustness Check

We changed the dichotomously measured morningness in the benchmark analysis to a continuum scale because based on the idea proposed by Chelminski et al. (1997) that using a continuum scale for morningness-eveningness could provide richer information regarding the hypothesized relationships. We also used a different single self-reported question, as proposed by Dohmen et al. (2011), to measure risk preference, and generate an all-around factor to predict risky behaviour. In addition, we added both risk and time preference measures in all settings of regressions and path analyses, as risk and time are intertwined. It would be problematic to isolate risk attitude when examining the effect of time preference on certain behaviour (Andreoni and Sprenger, 2012), as uncontrolled risk can create present-biased choices or behaviour. By changing the measurements of the interested variables and increasing bootstrap sample size from 5,000 to 50,000, we intend to verify the robustness of the results.

The continuum form of morningness-eveningness (Circadian rhythm) ranges from 15 to 51, where a higher score indicates greater morning orientation. General risk preference is a single indicator with a higher score presenting a higher level of risk taking, ranging from 1 to 11.

We conducted a robustness check on hypotheses (H1, H2, H3, H4, H6), because these hypotheses were supported by the benchmark results. First, we tested the link between circadian rhythm and revolving credit card debt.

**Table A1.** The effect of circadian rhythm on likelihood of delinquent credit card payments in logistic regression.

</table>
Note: The dependent variable is delinquent credit card payments. This table reports the average marginal effect of logistic regression examining the effect of circadian rhythm on delinquent credit card payments. The sample is comprised of Chinese full-time employees who have been working for 3 to 8 years, randomly sampled from an online survey. *, **, and *** respectively indicate significance at 10% level (2-sided), 5% level, and 1% level. Pseudo R2 reports model fit.

The results recorded in Table A1 indicate that circadian rhythm is negatively associated with the possibility of delinquent credit card payments ($b=-0.012$, SE=0.003, $z=-3.37$, $p<0.01$), which supports Hypothesis 1.

Second, we tested whether time preference mediates the relationship between circadian rhythm and delinquent credit card debt. Table A2 conveys the results (bootstrapping coefficient of indirect effect=$-0.107$, bootstrapping SE=0.006, 95% CI = [-0.024, -0.001]), which supports Hypothesis 2.

Third, we set out to verify whether income moderates the time preference-delinquent credit card debt relationship, and whether the indirect effect of circadian rhythm on delinquent credit debt payments through time perspective, is moderated by monthly income, such that an indirect effect exists for those whose income is at low to average level. Table A3 reports the corresponding results, which supports Hypothesis 3 (The coefficient of interaction item monthly income*time preference=0.065, SE=0.028, $p<0.05$) and Hypothesis 4 (Index of moderated mediation=0.008, Boot SE=0.004, 95%CI=[0.001, 0.018]).

Note: Unstandardized regression coefficients are reported; bootstrap sample size=50,000. CI=confidence interval; LL=low limit; UL= upper limit. * indicates p<0.1, ** indicates p<.05, and *** indicates p<0.01.

Finally, we examined whether financial risk preference mediates the relationship between circadian rhythm and the likelihood of investments in the stock market. Table A4 shows the results (bootstrapping coefficient of indirect effect=0.010, bootstrapping SE=0.006, 95% CI=[0.0002, 0.022]) that support Hypothesis 6.

Table A4. The mediating effect of general risk preference on the relationship between circadian rhythm and stock market participation.

</tbody>
</table>

Note: Unstandardized regression coefficients are reported; bootstrap sample size=50,000. CI=confidence interval; LL=low limit; UL= upper limit. * indicates p<0.1, ** indicates p<.05, and *** indicates p<0.01.

To summarize, after changing the measures of morningness-eveningness, and the measure of risk preference, the results are robust and support the findings in the benchmark analysis.
