We demonstrate a technique to estimate the strength of non-linearities present in the trapping potential of an optically levitated nanoparticle. By applying a brief pulsed reduction in trapping laser power of the system such as to squeeze the phase space distribution and then matching the time evolution of the shape of the phase space distribution to that of numerical simulations, one can estimate the strength of the non-linearity present in the system. We apply this technique to estimate the strength of the Duffing non-linearity present in the optical trapping potential.

Non-linearities have been proposed to be used in optomechanical systems for inducing steady-state mechanical squeezing1, ground state cooling2, achieving sub-Poissonian statistics3 and generating non-Gaussian states4. It has been demonstrated that mechanical non-linearities can be mapped into the microwave domain by coupling with a Microwave superconducting coplanar waveguide (CPW) resonator5 and have been exploited to improve the figures of merit for nanotube and graphene resonators6.

For cantilever systems it has been proposed that one could use a Duffing non-linearity to observe classical to quantum transitions utilizing the bistable regime of such an oscillator7. Non-linearities have been utilized alongside frequency stabilization to achieve large amplitude and therefore large signal-to-noise ratio in MEMS devices8, to realize mechanical bit operations9,10 and to induce stochastic switching to boost detected signals11.

Non-linearities can also be exploited to differentiate between classical and quantum dynamics; as in a harmonic potential such behaviour is difficult to distinguish11,12. Precise control of the non-linear and stochastic bistable dynamics has been achieved for optically levitated nanoparticles within a Duffing potential and used to demonstrate stochastic resonance in good agreement with analytical models and utilized to amplify forces on the system13.

The method we describe here can be used to determine non-linearities which are inherent to the system14, as well as those introduced by external forces15,16 which perturb the potential. Estimating non-linearities of optomechanical systems is an area of interest and several methods have been proposed and utilized to probe non-linearities13,14,17.

In this paper we demonstrate characterization of the inherent Duffing non-linearity in the mechanical potential by applying an operation to the system where the power of the trapping laser is reduced rapidly for a brief pulse before being restored to the original power in such a way as to squeeze the phase space distribution of the system. We perform many such pulses and then match the resulting phase space distribution to numerical simulation in order to estimate the strength of the Duffing non-linearity. This method can be applied to any physical system where the phase space distribution can be squeezed and subsequently allowed to freely evolve in a region of phase space where non-linearities of the system affect the evolution. In this paper we find that a perturbation of the potential by a factor as low as \( \frac{1}{4} \) is sufficient for a visible effect on the phase space distribution.

The experiment was performed using the setup shown in figure 1. To perform a squeezing operation we first rapidly change the natural oscillation frequency from \( \omega_0 \) to \( \omega_1 \) then we let the system evolve for time \( \tau_{\text{pulse}} = \frac{\pi}{2\omega_1} \) before rapidly switching back to \( \omega_0 \). Such a frequency modulation is achieved using an acousto-optic modulator (AOM) to rapidly reduce the trapping laser power from \( P_0 \) to \( P_1 \) and, after a short delay, raise the power back to \( P_0 \).

In this particular experiment the translational motion parallel to the laser propagation direction was used, which had a natural frequency of \( 64.9 \pm 0.3 \) kHz and the power was decreased by \( 78.4 \pm 1.5 \% \) for \( 8.29 \) \( \mu \) s, which corresponds to a quarter of the natural frequency at the lower laser power during the pulse, which was \( 30.16 \pm 0.45 \) kHz. The squeezing pulse was applied and the then system allowed to relax while being measured. We performed this operation 500 times, measuring the photodetector current for each pulse and relaxation. If we then plot the ensemble of the points of position and velocity, accrued over the 500 operations, \( 83 \) \( \mu \) s after the pulse, we build up the phase space distribution shown in figure 2. These experiments were performed at a pressure of \( 0.164 \pm 0.025 \) mbar.

The spiral shape we observe in the phase space in figure 2 can be explained by the optical potential taking the form of a softening Duffing potential. The points where the particle is displaced further from the centre of the potential well experience a softer potential well with a

The motion of the nanoparticle in this potential is well described by the following classical stochastic differential equation:

\[
\dot{q} = -\Gamma_0 \dot{q} + [1+S_q](-\omega_0^2 q - \xi \omega_0^2 q^3) + \sqrt{\frac{2T_0 k_B T_0}{m}} dW
\]

where \(\Gamma_0\) is the damping on the system due to gas collisions, \(W\) is a real, zero-mean, Wiener process, \(T_0\) is the temperature of the surrounding gas environment and \(m\) is the mass of the nanoparticle. \(S_q\) is a term parameterizing the squeezing pulse and takes the following form:

\[
S_q = \begin{cases} 0.784, & \text{if } 0 \leq t \leq T_{\text{pulse}}, \\ 0, & \text{otherwise} \end{cases}
\]

This equation neglects the effects of photon recoil because the effect is negligible at the pressure range considered here.

From the experimental data we can extract the values of \(\omega_0 = 408 \times 10^3 \pm 4 \times 10^3\) s\(^{-1}\) and \(\Gamma_0 = 619 \pm 93\) Hz\(^{19}\) and we experimentally control the values of \(S_q\) which are applied to the system. We also assume \(T_0\) to be at room temperature, 300 K, as the gas inside the vacuum chamber is assumed to be in equilibrium with the environment. The range of \(m\) allowed was narrowed down by analyzing the data\(^{20}\) and then estimated more precisely to have a value of \(m = 4.8 \times 10^{-19}\) kg by matching to simulation. This can be done because the extent to which the phase space distribution is squeezed is affected by the mass, but the shape of the spiral is not, so with a higher mass one gets the same shape in phase space but the arms of the spiral are less densely populated and more clumped in the centre.

This leaves \(\xi\) as the only free parameter to vary in order to match the simulated phase space with the experimental phase space. The tightness of winding of the arms in the phase space distribution is determined by the effective frequency shift in the motion due to the strength of the Duffing term in the potential. As such the spiral shape in phase space is determined entirely by the magnitude of the Duffing term.

The phase space distribution accumulated over 400 simulated trajectories is shown in figure 3 for four values of \(\xi\), demonstrating the relationship between \(\xi\) and the tightness of the spiral. As the non-linearity strength, \(\xi\), increases so does the gradient with which the frequency of the motion changes with position. In addition the trapping potential is plotted for the four values of \(\xi\).

By taking the experimental and simulated phase space points a certain time after the pulse has finished one can compare their distributions using a Kolmogorov-Smirnov statistical test. This test returns a P-value on the null hypothesis that the two sets of points are drawn from the same distribution. This P value can be maximized to find the Duffing parameter \(\xi\) for which the simulated phase space distribution best matches the experimental distribution. In order to find the value of \(\xi\) for which the simulation best matches the experimental data we ran
In conclusion we have performed squeezing pulses on experimental data points and 400 simulated data points 77.5µs after the squeezing pulse for a range of 300 values of ξ along with the same data with a smoothing Savitzky-Golay filter applied and the Guassian one obtains when fitting this data to extract the statistical mean and standard deviation.

For the non-linear component of the potential to dominate over the harmonic component at a particular displacement q one requires that \( \xi > \frac{1}{2q^2} \). If one takes for example a displacement of 500 nm, where in the phase space distribution the non-linear component can be seen to begin having a visible effect, one calculates that a \( \xi \) of 4 \( \mu \text{m}^{-2} \) is the critical value above which the non-linearity would dominate the potential. We remark that the \( \xi \) value we extract is much lower than this, meaning a dominant non-linear effect is not necessary for the non-linearity to have a significant effect on the dynamics of the phase space distribution’s evolution and for the method we have described here to be applicable.

For a chosen \( \xi \) value the P value can be plotted over time after the pulse, for the \( \xi \) we find to be the best fit, \( \xi = -0.100 \mu \text{m}^{-2} \), we obtain the plot of the P-value over time shown in figure 6. From this figure one can observe that the P-value is distributed mainly above the 5% significance level. It can also be observed that the P-value grows over time after the pulse. The reason for this is that the experimental phase space distribution is extracted by performing a band-pass filter upon the photo-current data and this processing distorts the initial position and velocity data due to edge effects from the filter.

In conclusion we have performed squeezing pulses on the system to observe the spiral shape in the phase space distribution resulting from a Duffing non-linearity. We have then simulated the trajectory of motion of the system by numerically solving the stochastic differential equations modelling the system. By varying the unknown

FIG. 3: plots of phase space distributions 77.5 µs after the squeezing pulse with four different ξ values as well the potentials.

(a) phase space after 83 µs for \( \xi = 0.0 \mu \text{m}^{-2} \) in grey, \( \xi = 0.05 \mu \text{m}^{-2} \) in yellow, \( \xi = 0.1 \mu \text{m}^{-2} \) in green and \( \xi = 0.2 \mu \text{m}^{-2} \) in purple.

(b) Plot of the potential for the four values of \( \xi \) with the colors corresponding to 3a with \( \xi = 0.0 \) showing the harmonic component of the potential with no non-linearity present.

400 simulations for 300 different values of ξ and extracted the P-value for each, as can see seen in figure 4. We then applied smoothing and fitted a Guassian to this data in order to extract the statistical mean of \( \xi = -0.100 \mu \text{m}^{-2} \) with a standard deviation of \( \sigma_\xi = 0.054 \mu \text{m}^{-2} \).

The meaning of the negative sign on this value is that as displacement from the centre of the trap gets larger the natural frequency of the motion gets lower, this is because of the Gaussian profile of the laser beam, as you get further from the centre of the trap the gradient of the electric field decreases non-linearly. With the statistical mean value of \( \xi = -0.100 \mu \text{m}^{-2} \) for the Duffing non-
Duffing strength and matching the simulated phase space distribution to the experimental one we estimate the Duffing strength.

The advantages of this method are that it is repeatable and can be performed on command and it does not rely on stochastic excitations in order to explore the non-linear regime. It can also be performed at pressures from $1 \times 10^{-1} - 10^{-9}$ mbar as it does not rely on gas collisions to drive the system into the non-linear regime and only requires $Q$ factors high enough to observe the time evolution of the spiral shape for several oscillations. If performed at low pressures the high Q factor of the oscillator could in fact allow for more precise estimation of the non-linearity, since the spiral pattern will persist in the phase space for a longer time. In addition, feedback cooling can be applied while performing this procedure if the effect of the non-linearities are discernible at smaller displacements and if there is a risk of the particle escaping the trap.

This method to estimate non-linearities is also broadly applicable to a large range of physical systems such as levitated systems and Bose-Einstein condensates, and cantilever systems. This method can be used to estimate the magnitude of any kind of non-linearity with respect to displacement, as these affect the shape of the phase space distribution when a squeezing pulse is applied and the subsequent time evolution. In this way this method could be utilized to sense and quantify forces on the system.

A similar, more sophisticated, method to match these two would be to use Sequential Monte Carlo (SMC) methods to estimate the non-linearity as it can optimize the value of the non-linearity $\xi$ as it simulates the system to best match the measurement record, however, this is much more computationally intensive.
