4 Advances in Human Stem Cell Therapies: Pre-clinical Studies and the Outlook for Central  
5 Nervous System Regeneration

6

7 **Key words:** *cell transplantation, CNS regeneration, embryonic stem cells, induced pluripotent*  
8 *stem cells, spinal cord injury*

9

10

11 **Abstract:** Cell transplantation has come to the forefront of regenerative medicine alongside  
12 the discovery and application of stem cells in both research and clinical settings. There are  
13 several types of stem cells currently being used for pre-clinical regenerative therapies, each  
14 with unique characteristics, benefits and limitations. This brief review will focus on recent  
15 basic science advancements made with embryonic stem cells (ESCs) and induced pluripotent  
16 stem cells (iPSCs). Both ESCs and iPSCs provide platforms for new neurons to replace dead  
17 and/or dying cells following injury. Due to their capacity for reprogramming and  
18 differentiation into any neuronal type, research in preclinical rodent models have shown that  
19 ESCs and iPSCs can integrate, survive and form connections in the nervous system similar to  
20 *de novo* cells. Going forward however, there are some limitations to consider with the use of  
21 either stem cell type. Ethically ESCs are not an ideal source of cells, genetically iPSCs are not  
22 ideal in terms of personalised treatment for those with certain genetic diseases the latter of  
23 which may guide regenerative medicine away from personalized stem cell based therapies and  
24 into optimized stem cell banks. Nonetheless, the potential of these stem cells in CNS  
25 regenerative therapy is only beginning to be appreciated. For example, through genetic  
26 modification, stem cells serve as ideal platforms to reintroduce missing or downregulated  
27 molecules into the nervous system to further induce regenerative growth. In this article, we  
28 highlight the limitations of stem cell based therapies whilst discussing some of the means of  
29 overcoming these limitations.

32

### **Stem cells in nervous system repair**

Regeneration of the injured central nervous system (CNS), for example following spinal cord injury (SCI), is hindered by two main factors: an inhibitory environment surrounding the lesion site and the failure of mature neurons to regenerate. Current therapies for CNS injury produce only modest levels of physiological and functional neuronal repair highlighting a critical requirement for new treatments. One research area receiving significant attention involves replacing damaged cells and tissues with cell transplants. A range of cell types have recently been investigated for their potential to promote CNS repair including but not limited to oligodendrocyte precursor cells, olfactory ensheathing cells, bone-marrow derived stromal cells (BMSCs), neural progenitor cells (NPCs) (Reviewed in Tetzlaff et al., 2011), embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs). Although each of the above cell types have demonstrated some level of regenerative growth in rodent models of CNS injury either modestly or more substantially, it is stem cell transplants that hold the greatest therapeutic potential due to their capacity to produce any cell type. Several different types of stem cells induce regrowth and/or new growth after injury including ESCs, endogenous neuronal stem/precursor cells (NPCs/NSCs), BMSCs and iPSCs. This article, however, will focus on human ESCs and iPSCs and summarize the current approaches used to combat their limitations in promoting integration, survival and regeneration following CNS transplantation in animal models.

### **Human stem cells**

Human embryonic stem cells, or ESCs, develop from mammalian blastocysts and can differentiate into all three germ layers and thus any cell type (Evans and Kaufman, 1981). There are ethical concerns surrounding the acquisition and subsequent use of human ESCs that has limited their use both experimentally and therapeutically. Alternatively, induced pluripotent stem cells, or iPSCs, can be produced by inducing expression of defined transcription factors in somatic cells resulting in their dedifferentiation back to a pluripotent state (Takahashi et al., 2007) which can then be differentiated to any target cell type. Recent advances using iPSCs have demonstrated successful modelling of neurodegenerative and genetic diseases which surpass current methods as most knockout mice or toxin-induced models cannot fully reproduce disease pathology (Reviewed in Wu et al., 2019). Nevertheless, the discovery of iPSCs brought forward the idea of personalized medicine, where one's own cells could be used

65 as a treatment for diseases or injures, yet there are clear challenges involved in creating tailored  
66 cell therapies. Alongside extensive cost and time required to produce the cells, evidence  
67 suggests that reprogramming iPSCs has limitations including the epigenetic state of somatic  
68 cells as well as potential cellular senescence among others (Reviewed by Haridhasapavalan et  
69 al., 2019). Equally, in treatment of genetic diseases such as Huntington's disease, personalized  
70 iPSCs are likely to have little benefit to patients without genetic correction prior to therapeutic  
71 use (Reviewed by Golas and Sander, 2016). Perhaps a more practical option is the creation of  
72 stem cell banks which contain human donor stem cells screened for specific leukocyte antigens  
73 which can then be matched to individual patients (Reviewed in Solomon et al., 2015). Despite  
74 these limitations, however, iPSCs have the potential to be a significant resource for disease  
75 modelling and have thus far been used in rodent CNS transplantation studies with encouraging  
76 results.

### 77 Human-derived ESCs and iPSCs in rodent models of CNS repair

78 The generation of efficient human ESC-directed differentiation into specific neuronal subtypes  
79 *in vitro* well over a decade ago has opened new avenues for CNS disease modelling and cell  
80 replacement therapies. Transplantation of human ESC-derived cells into rodent models has had  
81 great success (Denham et al., 2012; Espuny-Camacho et al., 2013; Espuny-Camacho et al.,  
82 2018). For example, Denham and colleagues transplanted pre-differentiated neurons derived  
83 from human ESCs into the uninjured neonatal rat striatum at postnatal day 2. ESC-derived  
84 axons were detected along host white matter tracts, with *ex vivo* patch clamping of grafted  
85 neurons displaying action potentials, and immunohistological analysis revealing expression of  
86 synaptic proteins suggesting functional integration (Denham et al., 2012). Further  
87 advancements with human ESC-derived neurons indicate that matching the phenotype of  
88 transplanted stem-cell derived neurons to the cortical areal identity significantly improves graft  
89 viability and integration (Espuny-Camacho et al., 2018). For example, transplanted human  
90 ESC-derived visual cortical cells functionally integrated into the lesioned mouse visual cortex  
91 forming functional synapses with host circuitry compared to visual cortical cells transplanted  
92 into the mouse motor cortex which had limited integration with host circuitry (Espuny-  
93 Camacho et al., 2018).

94 *In vitro* studies of human iPSCs have further paved the way for the advancement of stem cell  
95 transplantation into the CNS. For example, cerebral cortical neurons can be generated from  
96 human iPSCs *in vitro* (Shi et al., 2012). These iPSC-induced pyramidal cells not only form

97 neurons from several cortical layers, they produce a glutamatergic phenotype, form excitatory  
98 synapses and possess electrical activity *in vitro* (Shi et al., 2012). Similarly, human iPSCs and  
99 their derivatives have shown great promise following CNS transplantation (Tornero et al.,  
100 2013; Forbes and Andrews, 2019). In the context of injury, transplants of human cortically-  
101 fated iPSC-derived NPCs into the rat somatosensory cortex following stroke-induced injury  
102 resulted in functional recovery with evidence of integration into the immunocompromised host  
103 brain (Tornero et al., 2013). Interestingly, transplanting cortically-fated iPSC-derived cells  
104 compared to un-fated iPSC-derived neural progenitors resulted in fewer proliferating cells  
105 (detected with Ki67 immunohistochemistry) likely reducing the risk of tumour formation  
106 although both graft types resulted in comparable functional recovery (Tornero et al., 2013). On  
107 the other hand, only the cortically-fated iPSC-derived cells extended high density projections  
108 following grafting suggesting that cellular identity increases integration and function as  
109 described for human ESCs. This was shown in a recent study where human iPSC-derived NSCs  
110 were injected alongside an artificial extracellular matrix into the sensorimotor cortex of  
111 perinatal rats following induced focal ischemia (Basoudan et al., 2018). A month after grafting,  
112 instead of dispersing and projecting into the host environment as documented *in vitro*,  
113 transplanted cells formed cerebral organoids characterized by neural stem and progenitor cells  
114 generating rosettes, failing to extend long distance projections. As these cells were un-fated  
115 neural stem cells, they likely were unable to differentiate further and instead remained in a stem  
116 cell niche highlighting the requirement for areal specific fated cells for CNS transplantation.  
117 Furthermore, both inhibitory and excitatory cortical neurons can be generated from human  
118 iPSCs *in vitro* and, following transplantation into the uninjured adult rat forebrain, can exhibit  
119 both inhibitory and excitatory post-synaptic currents (Yin et al., 2019). This suggests human  
120 iPSC-derived neurons could re-establish damaged signaling pathways following injury.

### **Combating the limitations of stem cell grafts**

122 There are limitations surrounding stem cell transplantation research which in turn can  
123 substantially limit their use long-term. Two of the major limitations are graft survival and  
124 integration into the host environment. **Much can be learned from mouse stem cell transplants  
125 into mouse hosts, but with the current availability of human iPSCs it is crucial to explore the  
126 survival and regenerative capacity of human cells in a rodent host. To fully understand the  
127 capabilities of human iPSCs to promote CNS repair, pre-clinical xenogenic transplant models  
128 are frequently chosen but often require modification of the host immune system.** Currently this

129 modification involves the use of immunodeficient hosts such as NOD/SCID transgenic mice,  
130 or the use of immunosuppressant drugs such as cyclosporine. However, transplantation of  
131 human stem cells into naïve neonatal rodents (postnatal day 0 – postnatal day 3) increases graft  
132 survival due to the immature state of the immune system and allows fundamental  
133 characterization of grafted cells *in vivo*. For example, we have observed that human iPSC-  
134 derived NPCs could survive up to 8 weeks post-transplantation into the uninjured neonatal (P0-  
135 P2) cerebral cortex (Forbes and Andrews, 2019). Others have reported similar survival rates  
136 with human ESC-derived neurons, with survival up to 10 weeks post-transplantation into the  
137 neonatal uninjured rat striatum (Denham et al., 2012).

138 In order to prolong the survival of human stem cell grafts *in vivo* we can gain insight from  
139 mouse stem cell transplant studies. A recent study has utilized a strategy for inducing  
140 immunological tolerance of transplanted mouse-derived stem cells to increase graft survival.  
141 Specifically in this study, Li and colleagues examined allogeneic stem cell transplantation  
142 together with modulation of T-cell activation in the host, results of which demonstrated a  
143 significant increase in grafted cell survival (Li et al., 2019). In other studies, Ballout and  
144 colleagues have shown that a mouse stem cell transplant can modify the local environment,  
145 whereby transplanted cells increased recruitment of astrocytes (Ballout et al., 2019), which are  
146 known to be associated with axon growth and guidance, suggesting cell grafts stimulate a pro-  
147 regenerative environment. They also demonstrated that delaying the timing of transplantation  
148 after injury in an adult mouse host improves graft survival as this avoids the immediate immune  
149 response occurring in the injury. For example, one week following lesioning of adult mouse  
150 motor cortex, embryonic-derived motor neurons were transplanted into the lesion site. At one  
151 week post-lesion, there was an increased presence of pro-regenerative cells, such as Arg1-  
152 immunoreactive microglia, and a decrease in pro-inflammatory cytokines, such as interleukin-  
153 1 $\beta$ , likely resulting in increased chances of graft integration and viability. At 21 days post-  
154 injury however, pro-regenerative microglia switch to a pro-inflammatory phenotype narrowing  
155 the window for therapeutic intervention (Ballout et al., 2019). These results highlight the pro-  
156 regenerative aspects of neuroimmune cells, such as microglia and astrocytes, but recognize the  
157 limitations of the host immune system. Together these results suggest that repair of CNS  
158 injuries using stem cell grafts may be possible, yet highlights the host immune system may  
159 dictate therapeutic timing.

160 In animal models of CNS injury, although graft survival can often be prolonged with  
161 immunosuppression or neonatal immune-deficient windows, survival is also influenced by the  
162 ability of grafts to integrate within host tissue. In some CNS injuries, for example SCI, the  
163 environment of the injury site can prevent cell integration and thus survival due to an increase  
164 in inhibitory proteins within the lesion including those associated with the glial scar, containing  
165 reactive astrocytes that secrete the proteoglycan tenascin-C and chondroitin sulphate  
166 proteoglycans (CSPGs). Modifying or pre-conditioning stem cells prior to transplantation may  
167 better equip cells to adapt within an inhibitory environment and result in better repair. For  
168 example, overexpression of growth-promoting proteins such as integrins to promote axonal  
169 growth (Forbes and Andrews et al., 2019), specifically the  $\alpha 9$  integrin subunit in human iPSC-  
170 derived NPCs, resulted in increased neurite outgrowth on a tenascin-C substrate *in vitro*. In  
171 other studies, co-delivery of Chondroitinase ABC, an enzyme which degrades CSPGs, has been  
172 shown to increase in transplant survival when delivered to a spinal cord lesion together with  
173 human induced pluripotent stem cell-derived neuroepithelial cells (Führmann et al., 2018). In  
174 addition to increased stem cell transplant survival, ChABC delivery also led to the development  
175 of functional synapses and behavioural recovery after SCI when delivered with mouse iPSC-  
176 NPCs (Suzuki et al., 2017). This highlights the potential for combining treatments that can  
177 combat the inhibitory environment created after CNS injury with a human stem cell  
178 replacement therapy to promote repair when used in an injury model.

179 To further enhance human graft viability, cell replacement therapies however could evolve  
180 from single stem cell transplants and instead focus on tissue-based transplantation consisting  
181 of more developed stem cell structures, such as pre-developed axon tracts (Chen et al., 2019)  
182 or organoids (Daviaud et al., 2018). Human ESCs organoids have been established from  
183 human ESCs *in vitro* and following transplantation into the lesioned mouse cortex demonstrate  
184 enhancement of graft viability compared to single cell transplants (Daviaud et al., 2018).  
185 Further benefits of this organoid tissue-based transplantation include a reduction in  
186 microglia/macrophage activity and increased vascularization to the grafted organoids  
187 compared to human NPC grafts.

188 New methods are further being developed to promote axon growth prior to transplantation.  
189 This includes axon stretch growth which elongates stem cell-derived axons prior to  
190 transplantation (Chen et al., 2019). By growing human stem cell-derived NPCs on a moving  
191 membrane and exposing them to mechanical tension, axon tracts can be grown within the

192 laboratory extending up to 1 cm in a month. *In vitro* these tracts demonstrate functional activity  
193 with spontaneous calcium waves (Chen et al., 2019). This offers new *in vitro* methods for  
194 modeling CNS injury and a further possibility for transplantation of axon tracts providing new  
195 hope for navigating the intrinsic inabilities of axons to promote growth after injury. Pre-formed  
196 axon tract replacement however, does not address how transplanted tracts would merge and  
197 synapse with existing, potentially multiple, damaged tracts *in vivo* and would likely also require  
198 modification of the local injury environment.

199 Together these studies stress the potential that human stem cells have for overcoming both graft  
200 survival and integration into the injured CNS. Yet there are still a number of stark challenges  
201 surrounding cell replacement therapy namely ethical use of human stem cells and ensuring  
202 proper quality control. Similarly, in this article we have focused on pre-clinical human stem  
203 cells *in vitro* and following transplantation into CNS injury animal models yet the physiological  
204 processes underlying human CNS injury are vastly more complex highlighting the requirement  
205 for more reliable and robust pre-clinical and clinical models to ascertain the extent to which  
206 human stem cells can promote CNS repair.

## 207 **Conclusions**

208 Human stem cell grafts hold great promise for CNS treatments with potential for patient-  
209 specific therapies in CNS diseases and injuries. Due to the complexity of many CNS  
210 conditions, such as SCI, it is likely research will focus on structured tissue-based  
211 transplantation approaches due to promising integration and survival. Furthermore, careful  
212 consideration of the immune response must be tailored to provide a pro-regenerative window  
213 for therapeutic intervention. This timed treatment would likely be in combination with pre-  
214 conditioning e.g. cell adaptations *in vitro* prior to transplant, or pharmacological interventions  
215 to modify the inhibitory injured environment.

216 It is expected that the different diseases will have different requirements for stem cell therapy.  
217 For example, where neuronal cell death is a crucial disease characteristic, such as Alzheimer's  
218 and Parkinson's disease, the focus for therapy would likely be replacing injured or damaged  
219 neurons, whereas in other conditions the therapeutic focus may center on promoting  
220 endogenous repair or via secretion of pro-regenerative factors. In some injuries, such as SCI, a  
221 combination of these strategies may be required to promote functional repair.

**224 Figure legend: Recent stem cell transplantation studies.** Embryonic stem cells are derived  
**225** from the inner cells of mammalian blastocysts. This is in comparison to induced pluripotent  
**226** stem cells which are derived from somatic cells, such as fibroblasts, that are dedifferentiated  
**227** back to a pluripotent state *in vitro*. Both ESCs and iPSCs have the potential to be differentiated  
**228** into any cell type with iPSCs holding a great advantage for prospective tailored cell therapy.
