Abstract

The widespread occurrence of lower Eocene chert and porcellanite has been viewed as a major paleoceanographic issue since the advent of ocean drilling, and both biotic and abiotic forcings have been proposed to explain it. We present a reconstruction of indurated siliceous sediment (ISS) and preserved biosiliceous sediment (PBS) occurrences in the Atlantic Ocean through the Paleocene and Eocene (~66 through 34 Ma). ISS and PBS distributions reveal dissimilar temporal trends, with the peak of ISS occurrences coinciding with the Early Eocene Climatic Optimum, in line with previous studies. PBS occurrences show a generally increasing trend culminating between 44 and 43 Ma. The common co-occurrence of ISS and PBS, and their coherent geographic distribution lends strong support to the biogenic origin of the precursor to the widespread Paleogene ISS, and argues against an inorganic mode of early Cenozoic chert and porcellanite precipitation. Weight per cent biogenic opal records and trends in linear sedimentation rates indicate two plausible modes of silicification: 1) silicification due to prolonged exposure of

biogenic opal-rich sediments to corrosive bottom waters; and 2) silicification due to elevated pressures and temperatures caused by rapid burial of biogenic opal-rich deposits. The confinement of ISS and PBS to proximal sites along continental margins points to the reliance of siliceous sedimentation through the Paleocene and Eocene on terrestrial supply of dissolved silicon. Consistent with this, quantitative siliceous microfossil assemblage records from the Blake Nose in the NW Atlantic indicate that the nutrient-rich marginal rather than oligotrophic pelagic settings hosted the majority of siliceous plankton production through the early Paleogene.

The inorganic SiO₂ precipitation model is unlikely to have been the dominant mechanism responsible for ubiquitous occurrences of early Paleogene ISS. We favor the biogenic ISS precursor scenario and reconcile it with the low-productivity early Cenozoic oceans by showing that large volumes of biogenic silica were supplied to the western North Atlantic Ocean from the North American margin through the Paleocene and Eocene. Dissolution of this surplus silica was facilitated by an early southwestward flow of young, SiO₂-depleted waters from the North Atlantic. All these factors contributed to ISS and PBS focusing in the western North Atlantic through the early Paleogene.

1. Introduction

The lower Paleocene through upper Eocene (hereafter abbreviated as P+E) deep-sea and onshore sedimentary record shows evidence for widespread SiO₂ deposition, including geographically extensive marine and freshwater diatomite (e.g., Oreshkina and Aleksandrova, 2007; Mach and Dvořák, 2011), deep-sea diatom and radiolarian ooze (e.g., Gombos, 1977; Nishimura, 1987), siliceous nannofossil ooze and chalk (e.g., Fourtanier, 1991), and chert and porcellanite (e.g., Hein et al., 1990; Muttoni and Kent, 2007). This interval is also the most recent example of a global greenhouse climate, with atmospheric *p*CO₂ levels estimated at 500-1000 ppmv (e.g., Foster et al., 2017) and surface and ocean temperatures approximately 10°C higher than modern (e.g., Zachos et al., 2001). In recent years there is a growing interest in the links between the silicon and carbon cycles, and the timescales of marine silica burial response to the extreme climate perturbations of the early Paleogene, with most insights based on modelling and stable isotope geochemistry (e.g., Penman, 2016; Penman et al., 2019; Fontorbe et al., 2020). Reconstructing biogenic silica (hereafter bioSiO₂) burial and diagenetic history may help unravel the interplay between weathering regimes, primary production and ocean circulation patterns (e.g., Miskell et al., 1985; Hein and Parrish, 1987; Maliva et al., 1989; McGowran, 1989; Yool and Tyrrell, 2005; Penman, 2016; Penman et al., 2019) through a critically important period of Earth's climate evolution (Zachos et al., 2008; Cramer et al., 2009).

69 The widespread occurrence of roughly coeval indurated siliceous sediments of early Eocene
70 age often collectively referred to as Horizon A^C (e.g., Riech and von Rad, 1979; Norris et al., 2001;
71 Boyle et al., 2017) was one of the key targets of early scientific deep-sea drilling (e.g., Ewing et al.,
72 1970). Multiple hypotheses have been put forward to explain the origin of this ubiquitous
73 silicification. Berger (1970) pointed to basin-to-basin bioSiO_2 fractionation by means of lagoonal
74 (Atlantic) versus estuarine (Pacific) circulation. Under this scenario, the Pacific nutrient-rich deep
75 waters favored bioSiO_2 preservation, while the Atlantic nutrient-poor deep waters facilitated bioSiO_2
76 dissolution. Gibson and Towe (1971) postulated diagenetic alteration of pyroclastic material and
77 speculated on its possible effects on siliceous plankton production, whereas Weaver and Wise
78 (1974) argued for an entirely biogenic origin of the chert/porcellanite precursors. More complex
79 models invoking, for instance, reprecipitation of bioSiO_2 leached by advecting hydrothermal waters
80 (Moore, 2008a, 2008b) were also proposed. Two hypotheses that have drawn the most interest,
81 however, were proposed by McGowran (1989) and Muttoni and Kent (2007).

82 The „silica burp hypothesis” of McGowran (1989) linked the widespread early Paleogene
83 silicification to volcanic SiO_2 input, followed by enhanced ocean mixing driven by long-term ocean
84 cooling through the Eocene. Silicon cycle modeling by Yool and Tyrell (2005), however, indicated
85 that “silica burp” was not sufficient to explain neither the large volumes of SiO_2 making up Horizon
86 A^C, nor the temporal span of the widespread early Paleogene silicification. Instead, Muttoni and
87 Kent (2007) proposed a complex model invoking clay mineral-mediated inorganic precipitation of
88 SiO_2 from seawater. One of the main assumptions that Muttoni and Kent (2007) made was that the
89 early Paleogene oceans were characterized by largely oligotrophic conditions. At the same time,
90 Muttoni and Kent (2007) hypothesized there would be an ample supply of SiO_2 from terrestrial
91 weathering, accelerated by the extreme greenhouse warmth of the early Paleogene. In a stratified
92 water column, the low supply of additional limiting nutrients like Fe, N, and P would prevent
93 siliceous phytoplankton from blooming even in SiO_2 -rich waters. Hence the inorganic mode of SiO_2
94 precipitation proposed by Muttoni and Kent (2007).

95 The above views on chert and porcellanite origin can be simplified to two general scenarios
96 - biogenic versus inorganic - to explain the ubiquitous early Paleogene silicification. The biogenic
97 scenario, in which bioSiO_2 accumulates on the seafloor and undergoes diagenetic alteration into
98 cristoballite and ultimately quartz, should be viewed as more parsimonious: bioSiO_2 is a common
99 skeletal material that is known to easily undergo dissolution in transit through the water column, at
100 sediment-water interface, and within the sediment (e.g., Kastner et al., 1977; Kennett, 1982;
101 Ragueneau et al., 2000; DeMaster, 2014; Tatzel et al., 2015). Biogenic origin for the early
102 Paleogene chert and porcellanite precursor, however, has been criticized on the grounds of the

103 purported low productivity of the early Cenozoic oceans (Muttoni and Kent, 2007). Inorganic SiO₂
104 precipitation requires high dissolved SiO₂ concentrations in seawater (Yool and Tyrrell, 2005).
105 Ocean waters were likely supersaturated with respect to SiO₂ in the Proterozoic, but the
106 Phanerozoic evolution of siliceous biota has caused the oceans to become SiO₂-undersaturated at all
107 depths (Maldonado et al., 1999; Conley et al., 2017). Thus, inorganic SiO₂ precipitation from
108 seawater would require a prolonged period of highly unusual oceanographic conditions during the
109 early Cenozoic. As neither the biogenic nor the inorganic scenario has received definitive support,
110 the source of SiO₂ required for the formation of geographically extensive bodies of indurated
111 siliceous sediments in the early Paleogene remains a matter of debate (e.g., Barron et al., 2015).

112 Previous studies suggest that the best perspective on the various aspects of SiO₂
113 accumulation may be gained from early Paleogene sediments of the Atlantic Ocean. For much of
114 the early Paleogene, the Atlantic was the main locus of biosiliceous sedimentation (Miskell et al.,
115 1985; Baldauf and Barron, 1990; Penman et al., 2019), which explains why most records of early
116 Cenozoic siliceous phytoplankton are preserved there (Barron et al., 2015). The Atlantic is also host
117 to the majority of early Paleogene chert and porcellanite deposits reported in the deep-sea drilling
118 literature (Muttoni and Kent, 2007; updated in Penman et al., 2019). To date, however, this
119 coincidence has not been subject to closer scrutiny.

120 The aim of the present work is to test the inorganic precipitation scenario for the early
121 Paleogene chert and porcellanite by exploring the links between P+E biosiliceous sedimentation,
122 and the formation of indurated siliceous deposits within the Atlantic Ocean. To this end, we present
123 (1) a new compilation of P+E indurated siliceous deposit occurrences in deep-sea cores taken from
124 the Atlantic Ocean; (2) a new compilation of biogenic siliceous deposit occurrences in these same
125 cores; and (3) new quantitative records of P+E siliceous microfossil abundance in the western North
126 Atlantic. Based on these data, and using published geochemical records, we provide an integrated
127 perspective on early Paleogene siliceous sedimentation in the Atlantic Ocean.

128

129 **2. Materials and methods**

130 *2.1. Terminology*

131 Despite the well-known petrographic differences (Calvert, 1977), this study makes no
132 distinction between chert and porcellanite, in order to correct for any inconsistencies in lithologic
133 descriptions that may have occurred over several decades of ocean drilling that generated the data
134 compiled herein. Chert, porcellanite, silicified limestone and silicified mudstone are here referred to
135 collectively as ‘indurated siliceous sediments’, abbreviated as ISS. We use the term ‘preserved
136 biosiliceous sediments’ (abbreviated as PBS) for all Atlantic occurrences of P+E siliceous

137 microfossils (radiolarians, diatoms, silicoflagellates, ebridians, synurophyte scales and siliceous
138 dinoflagellates) reported in the deep-sea literature, and those examined here. This includes not only
139 occurrences of well-preserved assemblages, but also those in-situ occurrences that are reported as
140 moderately or poorly preserved. Occurrences reported as reworked are not considered.

141

142 2.2. Chronology

143 All ages reported in this paper are relative to the Gradstein et al. (2012) timescale (hereafter
144 referred to as GTS2012). Age control was established only for those Atlantic Ocean sites that
145 recovered P+E ISS or PBS, or both. Published age models were used whenever available. These
146 were readjusted to GTS2012 if required. For sites lacking published age data, new age models were
147 compiled based on magnetostratigraphy, and/or foraminiferal, calcareous nannofossil, and
148 radiolarian biostratigraphic events. Wherever available, cyclostratigraphic data were incorporated
149 into the age models. For some intervals, especially in early DSDP holes, age control should be
150 considered approximate. To account for this, in each ISS/PBS deposit dataset a median is plotted
151 superimposed on a gray area that denotes the difference between sites with reliable age control and
152 sites with approximate age control. Information on all age models used and compiled for this study
153 can be found in Tables S1-S15 in the online Supplementary Materials.

154

155 2.3. Atlantic P+E ISS and PBS occurrence compilation

156 The compilation, designed to distinguish between those P+E sites that recovered ISS, and
157 those at which no such sediments were recovered, is based on a literature survey involving all
158 DSDP, ODP and Integrated Ocean Drilling Program (IODP) sites drilled in the Atlantic Ocean. A
159 detailed description of the compilation is presented in the online Supplementary Materials (Table
160 S16 and Supplementary Text).

161 Data on siliceous microfossil occurrences (termed PBS) were tabulated from shipboard
162 reports and post-cruise publications. Our compilations of ISS and PBS occurrences are presented in
163 Figs 1-3 in the main text and Fig. S1 and Tables S18-S19 in the online Supplementary Materials.
164 An extended P+E Atlantic site dataset, including the relevant reference lists and information on age
165 models, can be found in Tables S1 and S16 in the online Supplementary Materials.

166 All maps included in this paper were plotted on Ocean Drilling Stratigraphic Network
167 (www.odsn.de) base maps. For the geographic distribution analysis of both ISS and PBS, sites were
168 grouped into 10° latitude × 10° longitude bins based on their present-day geographic coordinates. A
169 matrix of eighteen latitude bins (90°S through 90°N) × twelve longitude bins (100°W through
170 20°E) was established to enable plotting the results in the form of a map.

171

172 2.4. *Quantitative siliceous microfossil assemblage records*

173 Samples from ODP Holes 1050A,C 1051A and 1053A (Blake Nose, western North
174 Atlantic), used for siliceous microfossil examination, were freeze-dried and processed following the
175 technique used in studies by Witkowski et al. (2012, 2014). Siliceous microfossils (diatoms,
176 radiolarians, silicoflagellates, ebridians, chrysophyte cysts, synurophyte scales and siliceous
177 dinoflagellates) were examined and counted using light microscopy. Absolute abundances were
178 established following the method outlined in Witkowski et al. (2012). Due to the large amount of
179 micropaleontological data collected, detailed taxonomic accounts will be published separately.
180 Here, we present only the data relevant to this study (see Table S17 in the online Supplementary
181 Materials).

182

183 **3. Spatial and temporal distribution of P+E Atlantic siliceous sediments**

184 3.1. *Geographic distribution*

185 3.1.1. *Indurated siliceous sediments*

186 Out of 190 sites in the Atlantic Ocean that recovered P+E intervals, occurrences of ISS are
187 documented at 83 sites (Fig. 2; Fig. S1; Table S1). These are confined to between ~65°S and ~57°N
188 (Fig. 1A; Fig. S1A). In the North Atlantic, P+E ISS occur in each 10° latitude × 10° longitude bin
189 adjacent to the South American and North American coast, including the Caribbean and the Gulf of
190 Mexico (Fig. 1A). Similarly, P+E ISS occur within each bin adjacent to the coasts of West Africa
191 and Europe from the western Gulf of Guinea in the south to Rockall Plateau in the north (Fig. 1A;
192 Fig. S1A). In the South Atlantic, ISS occurrences are patchy, and mostly associated with
193 topographic highs, including the São Paulo Plateau (Site 356), Rio Grande Rise (Site 357), Walvis
194 Ridge (Sites 525-529, 1266), Northeast Georgia Rise (Site 698), Islas Orcadas Rise (Site 702),
195 Agulhas Ridge (Site 1090), and Maud Rise (Site 689) (Fig. 1A; Fig. S1). Wherever present, ISS
196 occurrences average 2.8 per 10° latitude × 10° longitude bin. Consistent with previous studies
197 (Muttoni and Kent 2007), the highest number of ISS occurrences is reported from a crescent-shaped
198 area encompassing the Caribbean, Gulf of Mexico, and the Western North Atlantic (Fig. 1A; Fig.
199 S1A), between 10° and 40°N, and between 60° and 90°W (Figs S1A; S2A). Peak ISS frequency is
200 observed along the eastern North American seaboard (Fig. 1A; Fig. S1), including Hatteras Abyssal
201 Plain (Site 603), New Jersey continental rise and slope (Sites 605, 612, 613, 903-904) and Blake
202 Nose (Sites 1049-1052) areas (Fig. 1A; Fig. S1).

Although the bin resolution gives a rather coarse representation of ISS distribution, the documented occurrences of P+E ISS are confined to proximal sites. No ISS are reported from P+E sites located closer to the axial zone of the Atlantic Ocean (Fig. 1A).

3.1.2. *Preserved biosiliceous sediments*

P+E PBS are found at 70 sites in the Atlantic Ocean (Fig. 2; Fig. S1; Table S1). These are confined to between ~70°S and ~80°N (Fig. 1B). As previously observed for ISS occurrences, Atlantic sites with P+E PBS occur in settings proximal to the coasts of all continents, and are absent from the axial part of the Atlantic Ocean (Fig. 1B). In the North Atlantic, P+E PBS are found in each 10° latitude × 10° longitude bin adjacent to the South American and North American coasts between the equator and 50°N, including the Caribbean and the Gulf of Mexico (Fig. 1B). Along the eastern margin of the Atlantic Ocean, there are two zones of P+E PBS occurrences. The northern zone, between 40°N and 80°N, includes Vøring Plateau (Sites 338, 340, 343), East Greenland Basin (Site 913), Bay of Biscay (Sites 400, 402), Rockall Plateau margin (Site 406), Pendragon Escarpment (Site 549), and Edoras Basin (Sites 552, 553). The southern zone is in the equatorial and subtropical Atlantic between 0° and 20°N (Fig. 1B) and includes sites located on Sierra Leone Rise (Sites 13, 366), and within Cape Verde Basin (Site 367) and Kane Gap (Site 660). In the South Atlantic, a belt of P+E PBS extends along the South American coast from 10°S to 70°S, continuing as a prominent longitudinal belt between 60°S and 70°S (Fig. 1B). The latter encompasses Sites 327, 511, 512, 698, 700, and 702. P+E PBS in the Southeast Atlantic are confined to few sites, again associated with basement elevations, including Maud Rise (Site 689), Meteor Rise (Site 703), and Agulhas Rise (Site 1090) (Fig. 1B). Overall, PBS occurrences average 2.0 per 10° latitude × 10° longitude bin, wherever present. The highest number of PBS occurrences is reported from the western North Atlantic between 30° and 40°N, and 70-80°W, i.e., along the ISS-rich North American margin (Fig. 1A vs 1B).

Thus, Atlantic Ocean P+E ISS and PBS distribution patterns are highly coherent. These sediment types co-occur at 46 of the investigated sites (Fig. 2; Table S1), which strongly suggests a causal link. More importantly, however, the proximal distribution of siliceous sediments of both types points to the largely overlooked significance of marginal settings in early Paleogene bioSiO_2 production and burial.

3.2. *Secular distribution*

3.2.1. *Indurated siliceous sediments*

Although we report ISS occurrences within P+E intervals from 83 sites, three sites (12, 138, and 140) are excluded from the following discussion due to lack of age control. The temporal distribution of P+E ISS in the Atlantic Ocean shows a sustained rise from the early Paleocene (Fig. 3A). A plateau is reached between 56 and 57 Ma, and persists across the Paleocene-Eocene boundary. A steep rise in ISS occurrences commences between 54 and 53 Ma. The highest number of ISS deposits is observed in the time bin between 51 and 50 Ma, i.e., within the latter half of Early Eocene Climatic Optimum (EECO) (Fig. 3A). This result is consistent with the global trend reported by Muttoni and Kent (2007). A steady decline in the number of P+E ISS deposits is observed after 50 Ma. Except for a plateau between 45 and 44 Ma, this trend persists to the late Eocene (Fig. 3A). Regional trends in ISS distribution through time are briefly discussed in the Supplementary Text (see also Fig. S2).

As previously discussed by Muttoni and Kent (2007), the secular distribution of P+E ISS occurrences appears inversely correlated with long-term trends in benthic foraminiferal $\delta^{18}\text{O}$ (Cramer et al. 2009) (Fig. 3A, 3D; 4A). The trends in ISS occurrences and $\delta^{18}\text{O}$ are in reasonably good agreement especially for the Eocene (Fig. 3A; 4A). Given the absence of extensive polar ice sheets generally assumed for the early Paleogene (Edgar et al., 2007; Anagnostou et al., 2016), this suggests a strong thermal control on the ISS formation in the Atlantic Ocean. However, considering the consistent geographic distribution of ISS and PBS discussed above, the good agreement between $\delta^{18}\text{O}$ and ISS occurrences through time also suggests enhanced bioSiO_2 dissolution by warm bottom waters bathing the continental margins (e.g., DeMaster, 2014; Frings, 2017; Wade et al., under review). Correlation between benthic foraminiferal $\delta^{13}\text{C}$ (Cramer et al., 2009) and secular distribution of P+E ISS occurrences is weak (Fig. 4C), implying no apparent links between the long-term carbon cycle trends and bioSiO_2 diagenesis in the Atlantic Ocean through the early Paleogene. A comparison of temporal trends in ISS distribution to the silicate weathering flux (SWF) modelled by Caves et al. (2016) displays a contrasting pattern, with a moderately strong inverse correlation for the Paleocene and a moderately strong positive correlation for the Eocene (Fig. 4E). Further, the peak in ISS occurrences lags peak SWF by 1-2 million years (myrs) (Fig. 3C). We discuss this discrepancy in more detail in Section 6.1.

3.2.2. Preserved biosiliceous sediments

The number of Atlantic Ocean PBS deposits shows a steady increase from the early Paleocene until a minor peak is reached between 58 and 57 Ma (Fig. 3B). Fewer PBS occurrences are recorded between ~57 and 53 Ma, when a prolonged increasing trend in the number of PBS deposits is initiated (Fig. 3B). This increase is interrupted only by a transient plateau at ~50 Ma,

followed by an interval of steep rise that culminates between 44 and 43 Ma (Fig. 3B). Following this, the number of PBS deposits decreases. A minor rise is observed only in the late Eocene (Fig. 3B). Thus, on a basin scale, the secular distribution of PBS shows a considerably different pattern than that observed for ISS (Fig. 3A vs 3B). The most notable difference is the fact that the interval of peak ISS occurrences coincides with an interval of generally low PBS frequency. Regional trends in PBS distribution through time are briefly discussed in the Supplementary Text (see also Fig. S2).

Muttoni and Kent (2007) also observed a generally inverse relationship between the frequency of ISS and siliceous microfossil occurrences through time. They argued that the paucity of diatom and radiolarian occurrences in early Paleogene deep-sea sediments suggested that abundant chert occurrences through the EECO required an inorganic mode of SiO_2 precipitation. Unlike Muttoni and Kent (2007), we interpret the overall inverse relationship between ISS and PBS occurrences through time to indicate ISS formation at the expense of PBS. This is consistent with the view that opal-A is temporally unstable and, under favorable pressure and temperature conditions and on long timescales, undergoes diagenetic alteration to opal-CT and subsequently quartz (Hesse, 1983; Hein et al., 1990; DeMaster, 2014; Frings, 2017).

The comparison between P+E PBS secular distribution and published stable isotope records is less straightforward than for ISS (Fig. 3B, 3D). Linear correlations are either weak or inconclusive (Fig. 4B, 4D). Further, through the Paleocene, PBS occurrences are strongly inversely correlated to the SWF model of Caves et al. (2016) (Fig. 3C). For the Eocene, there is a weak negative SWF-PBS correlation (Fig. 4F). We interpret these contrasting relationships to support the diagenetic origin of the P+E ISS: the correlations are inconclusive as the original pool of the Atlantic Ocean PBS is depleted due to diagenetic ISS formation

3.3. ISS and PBS co-occurrences vs wt% bioSiO_2 records and linear sedimentation rates

ISS co-occur with PBS at various levels at 46 sites, out of 70 PBS and 83 ISS sites considered here (Fig. 2). In order to gain a closer insight into these co-occurrences, we examine several multi-myr-long weight per cent (hereafter wt%) bioSiO_2 records from western North Atlantic sites that recovered both sediment types. Wt% bioSiO_2 and linear sedimentation rate (LSR) data are from Witkowski et al. (under review).

Site U1403 (J-Anomaly Ridge; Table S16) recovered discrete ISS horizons within a bioSiO_2 -rich interval that coincides with an interval of low LSRs (Fig. 5). Site 384, also located at J-Anomaly Ridge (Table S16), represents an extreme case of ISS coinciding with a prolonged period of deep-sea erosion at the Early-Middle Eocene transition. The two chert layers observed at the base of Core 384-5R occur within a bioSiO_2 -rich interval that includes up to three tightly-spaced

304 stratigraphic gaps (Aubry, 1995). Sediment-water interface exposure of bioSiO_2 to highly SiO_2 -
 305 undersaturated ocean waters is a well-known factor in SiO_2 dissolution (DeMaster, 2014; Frings,
 306 2017). Seafloor bioSiO_2 dissolution leads to pore water enrichment in silicic acid. Whereas part of
 307 the pore-water dissolved SiO_2 content is returned to the bottom waters as benthic flux (Van
 308 Cappellen et al., 2002), the remainder undergoes diagenetic alteration to opal-CT and, ultimately,
 309 quartz (Kastner et al., 1977). In today's oceans, both seafloor bioSiO_2 dissolution rate and benthic
 310 flux kinetics are dependent on a number of factors, including temperature, host lithology, and
 311 particulate matter supply (DeMaster, 2014). Given that in the early Paleogene water column
 312 temperature gradients likely differed from those of the Neogene and the Recent (with water column
 313 dissolution rate exceeding seafloor dissolution rate), the relationship between water-column and
 314 seafloor bioSiO_2 dissolution rates may have differed from today. Also, the benthic flux efficiency
 315 may have differed from today's, given the considerably warmer bottom water temperatures
 316 indicated by benthic foraminiferal $\delta^{18}\text{O}$ records (Zachos et al., 2001; Cramer et al., 2009).

317 At Site 1050 (Blake Nose), the siliceous microfossil-rich P+E section is unusually expanded
 318 and includes seven ISS levels associated with moderate and high bioSiO_2 concentrations. Two ISS
 319 levels (at ~62.40-62.43 Ma in Hole 1050C) fall within an interval of high LSRs (Fig. 5). These
 320 could represent a different mode of silicification, i.e., resulting from elevated pressure and
 321 temperature conditions due to rapid burial (see Riech and von Rad, 1979). The remaining ISS
 322 occurrences at Site 1050 are correlative with lower LSRs, lending further support to the importance
 323 of bioSiO_2 -rich sediment exposure to SiO_2 -undersaturated bottom waters in the formation of the
 324 widespread Atlantic P+E ISS.

325

326 *3.4. Recapitulation*

327 Three major conclusions can be drawn from the above review: 1) both ISS and PBS occur
 328 mostly in sites that are proximal to continental margins, and on basement elevations; Atlantic P+E
 329 sites located further offshore recover other sediment types, lacking ISS and PBS (Fig. 1, Fig. S1); 2)
 330 ISS and PBS occurrences show dissimilar distributions through time, with an overall increasing
 331 trend for PBS, and a prominent peak in ISS occurrences between 51 and 50 Ma. ISS and PBS co-
 332 occur at 46 sites, often over long time intervals (Fig. 2); 3) in most cases, ISS form discrete
 333 horizons within PBS intervals; these horizons often correlate with elevated bioSiO_2 levels and low
 334 LSRs (Fig. 5). These observations strongly suggest that ISS in the Atlantic Ocean are a product of
 335 diagenesis of bioSiO_2 -rich precursors. In order to set the above observations in the context of
 336 paleoproductivity, we proceed to discuss variations in siliceous microfossil assemblages as revealed
 337 by ODP sites 1050, 1051 and 1053 (Table S16). These sites are located on the Blake Nose, i.e.,

338 immediately adjacent to the area characterized by the highest frequencies of P-E ISS and PBS (Fig.
339 1A-B). Further, the Blake Nose sites are unique on a global scale in that they represent the most
340 continuous available record of biosiliceous sedimentation through the early Paleogene from a single
341 locality (Fig. 2) (Witkowski et al., 2020).

342

343 **4. Lower Paleocene through upper Eocene biosiliceous sedimentation at Blake Nose**

344 Siliceous microfossils are found throughout the studied successions at Blake Nose sites,
345 except for several narrow dissolution intervals (grey bands in Fig. 6), in which siliceous sponge
346 spicules and poorly preserved radiolarians are observed in the absence of siliceous phytoplankton.
347 At each study site, diatoms represent the dominant group of siliceous microfossils, making up on
348 average ~80.6% of the assemblage by number of individuals. Intervals of the highest total siliceous
349 microfossil abundance (hereafter referred to as TSM, following Witkowski et al., 2012) appear to
350 coincide with major periods of climatic and biotic turnovers: the final phases of the EECO (Luciani
351 et al., 2016; Westerhold et al., 2018), the peak of the Middle Eocene Climatic Optimum (MECO)
352 (Bohaty et al., 2009; Witkowski et al., 2014; Cramwinckel et al., 2019), and shortly after the
353 Middle-Late Eocene Turnover event (MLET) (Kamikuri and Wade, 2012). Interpreting the ~64.7
354 Ma peak in TSM abundance is problematic due to the missing earliest Paleocene record (Fig. 6A).
355 Sites that do preserve earliest Paleocene siliceous plankton, however, suggest enhanced biosiliceous
356 sedimentation in the period after the K/Pg event (Hollis et al., 1995).

357 The most notable feature of siliceous microfossil assemblages at the study sites are the high
358 diatom:radiolarian (D:R) ratios, which are considered a measure of the proportion of bioSiO_2
359 produced by diatoms versus radiolarians (Hollis et al., 1995; Renaudie et al., 2018) (Fig. 6B). D:R
360 ratios >200 are observed during the latest early Paleocene between ~61.2 and 62.8 Ma, an interval
361 encompassing the Latest Danian Event and its aftermath (LDE; Dinarès-Turell et al., 2012) (Fig.
362 6B). Following this, a steady, long-term decline is initiated, probably reflecting the increasingly
363 open marine depositional setting. The average D:R ratio value is ~25.5, and the rapid drops in the
364 D:R ratio coincide with diatom dissolution intervals (Fig. 6B). Thus, the relative enrichment in
365 radiolarians over these intervals is more likely due to non-preservation of diatoms rather than any
366 kind of rapid environmental change.

367 The most abundant diatoms at the Blake Nose sites are the neritic genera *Paralia* Heiberg
368 and *Pseudopodosira* Jousé (Fig. 6C). Together, these two genera make up on average 66.3% of the
369 diatom assemblage throughout the study interval (Fig. 6C). Except for the dissolution intervals, the
370 *Paralia* + *Pseudopodosira* percentages generally oscillate around the average level. We interpret
371 this unusually high proportion of neritic taxa in the open marine setting to signify persistent, high

372 diatom production on the North American margin combined with an efficient means of offshore
373 export, as observed today in the South Atlantic Bight region adjacent to the Blake Plateau (Lee et
374 al., 1991).

375 The pelagic genus *Hemiaulus* Heiberg has an average abundance of ~2.8% (Fig. 6D). There
376 are two intervals of elevated *Hemiaulus* percentages: from ~59 through ~56 Ma, and from ~47
377 through 45 Ma (Fig. 7D). The relative abundance of *Hemiaulus* is above average also from ~53.5
378 through ~50 Ma, which is bracketed by intervals of dissolution and silicification (Fig. 6D). It is
379 therefore likely that the whole period between ~59 and 45 Ma was characterized by elevated
380 abundances of hemiauloids, but the record was subsequently truncated by diagenetic processes.
381 Modern hemiauloids are adapted to nutrient-poor conditions (Kemp and Villareal, 2018), and in
382 paleoenvironmental reconstructions they are often considered as stratified water column indicators.
383 We interpret elevated hemiauloid percentages in the late Paleocene through the EECO, and in the
384 early phases of the middle Eocene cooling, to signify a long-term oligotrophic regime in the
385 western North Atlantic surface waters (Fig. 6D).

386 The average abundance of diatom resting spores in the whole study interval is ~6.4% (Fig.
387 6E); generally, resting spore percentages appear to be inversely correlated to hemiauloid
388 percentages (Fig. 6D vs 6E). Through the Paleocene and early Eocene, the resting spore percentage
389 is generally below average. From ~47 Ma, however, resting spore abundance generally increases
390 (Fig. 6E). We interpret this trend to reflect increased seasonality, with successive periods of nutrient
391 enrichment and depletion. This is consistent with invigorated vertical mixing of the western North
392 Atlantic waters from the onset of the long-term cooling trend shortly after the termination of the
393 EECO (Hohbein et al., 2012; Vahlenkamp et al., 2018; Witkowski et al., under review).

394 Variations in the Blake Nose siliceous microfossil assemblages suggest (1) a largely
395 oligotrophic setting in the pelagic zone of the Western North Atlantic Ocean for the Paleocene
396 through early Eocene period, and a post-EECO trend toward higher nutrient availability; (2)
397 persistent high diatom production along the North American margin, with an efficient means of
398 lateral transport of neritic diatoms into the open ocean zone by surface currents. We propose that
399 despite the low-nutrient regime prevailing in the Western North Atlantic Ocean for a prolonged
400 period in the Paleocene and early Eocene, these neritic diatoms represent the source of bioSiO_2 that
401 ultimately became dissolved and reprecipitated as ISS. This helps explain why the Western North
402 Atlantic hosts the largest volumes of ISS, but requires an interpretation in light of ocean circulation
403 changes, which follows below.

404

405 **5. Shifts in P+E Atlantic SiO_2 accumulation loci**

406 As a final aspect in our interpretation of P+E siliceous sedimentation in the Atlantic Ocean,
407 we use the wealth of data accumulated in this study to plot paleogeographic maps documenting how
408 the loci of siliceous sediment accumulation shifted through time (Fig. 7). Most importantly, the
409 maps indicate the areas of most persistent siliceous sediment accumulation through the P+E time
410 interval, but they also provide an integrated perspective on the links between biogenic siliceous
411 sedimentation and the formation of indurated siliceous deposits (Fig. 7). We include four time slices
412 in the main text, but a complete set of paleogeographic maps is provided in the online
413 Supplementary Materials (Fig. S3).

414 The earliest, most persistent and most geographically extensive zone of P+E bioSiO_2
415 accumulation in the Atlantic Ocean is found in the western North Atlantic (Fig. S3). It was
416 established at ~65 Ma, and initially represented by mid-latitude sites (Sites 1051 and U1403). By
417 the late Paleocene, however, the belt stretched along the entire eastern coast of North America (Fig.
418 7A). It reached its maximum geographic range between 51 and 50 Ma. By that time it extended
419 from the Colombian Basin in the SW (Site 29) to the Hatton-Rockall Basin in the NE (Site 117)
420 (Fig. 7B). The rapid expansion of this zone suggests an early flow of a proto-Gulf Stream
421 (Gradstein and Sheridan, 1983; Wade and Kroon, 2002) distributing nutrients along the North
422 American margin and sustaining bioSiO_2 production in the marginal part of the NW Atlantic. As the
423 North Atlantic broadened, the northern bioSiO_2 accumulation zone diminished, and eventually split
424 into a NW and NE sector (Fig. S3) following ~49 Ma. The NE P+E bioSiO_2 accumulation zone is
425 represented by few sites characterized by a discontinuous record (e.g., Holes 340; 400A; 406; 549;
426 see Table S1). The NW zone, however, persisted until the late Eocene, albeit with a diminished
427 geographic extent (Fig. 7C-D).

428 Another prominent SiO_2 accumulation zone is the South Atlantic belt at ~60°S. The
429 available evidence shows it was in existence from the earliest Paleocene to ~54 Ma, from ~52 to 50
430 Ma, and again from ~43 Ma to 34 Ma (Fig. S3). These breaks may represent periods of non-
431 preservation, but could also be due to plate tectonic reorganization associated with the Southern
432 Ocean gateways opening (Egan et al., 2013, Borrelli et al., 2014).

433 Two other P+E bioSiO_2 accumulation zones are identified within the Atlantic Ocean (Fig.
434 S3). The more persistent zone extended along the western coasts of Africa. By comparison to the
435 modern realm, it was most likely associated with the equatorial divergence and coastal upwelling
436 (Fig. S3). It appears to have undergone an extensive diagenetic alteration, as few sites within this
437 zone preserve biosiliceous sediments, mostly within the middle through late Eocene time bins (e.g.,
438 Sites 13, 366, 367, 660) (Fig. 7C-D, see also Fig. 2). The earliest siliceous deposits along African
439 coasts are recorded at northern and southern mid-latitude sites (e.g., Sites 530, 547) (Fig. S3).

440 bioSiO_2 accumulation at equatorial sites is not preserved until ~60 Ma, which may indicate that
441 equatorial divergence was not yet established, but it could also result from non-preservation. From
442 ~60 Ma on, however, the eastern equatorial Atlantic bioSiO_2 accumulation zone persisted until the
443 late Eocene (Fig. 7).

444 Southern mid-latitude bioSiO_2 accumulation was mostly associated with upwelling over
445 topographic elevations. SiO_2 accumulation at Walvis Ridge (e.g., Sites 524-530, 1266) (Fig. 7A-B,
446 Fig. S3) commenced at ~61 Ma and ceased at ~54 Ma, with an additional brief pulse between ~52
447 and 50 Ma. From ~54 Ma, southern mid-latitude bioSiO_2 accumulation shifted in a northwestward
448 direction, to Brazil Basin (Site 355), São Paulo Plateau (Site 356) and Rio Grande Rise (Site 357).
449 These locations preserve biosiliceous sediments until ~40 Ma (Fig. 7C vs 7D, Fig. S3).

450 Following ~30 myrs of gradual evolution, by the late Eocene, Atlantic bioSiO_2 accumulation
451 was focused in four zones: (1) NW, low- to mid-latitude sector; (2) NE, mid- to high-latitude sector;
452 (3) E equatorial sector; and (4) S high latitude belt (Fig. 7D). Especially the latter zone seems to
453 have undergone further evolution through the Oligocene and Neogene (Egan et al. 2013; Renaudie
454 2016), to become one of the world's most significant bioSiO_2 and C sinks (Fig. 7, Fig. S3).

455

456 **6. Discussion**

457 *6.1. Atlantic Ocean bioSiO_2 accumulation versus terrestrial silicate weathering through the early* 458 *Paleogene*

459 Silicon is mostly supplied to the oceans from continental weathering in the form of
460 dissolved silicic acid, and the key output flux in the marine silicon cycle is bioSiO_2 production,
461 export and burial (Tréguer and De La Rocha, 2013). Mass balance requires that the input be
462 balanced by output, most likely on a $\sim 10^4$ year timescale (DeMaster, 1981), i.e., the residence time
463 of Si in the oceans. Thus, the widespread occurrence of ISS in Paleogene successions, has been
464 interpreted by some workers to signify elevated rates of Si supply to the oceans (e.g., Yool and
465 Tyrrell, 2005). Under the extreme greenhouse climates of the early Paleogene, however, silicate
466 supply to the oceans may have undergone periodic acceleration, whose impact on climate and
467 bioSiO_2 accumulation in marine settings is not yet fully understood (e.g., Caves et al., 2016; van der
468 Ploeg et al., 2018).

469 Despite the important implications of the links between C and Si cycles (see Penman, 2016;
470 Penman et al., 2019), quantitative reconstructions of long-term bioSiO_2 burial through the early
471 Paleogene are sparse (e.g., Miskell et al., 1985; Moore et al., 2008; Witkowski et al., under review)
472 and therefore we have a limited perspective on the quantity and rate of Si supply to the oceans in
473 deep time. Further, the vulnerability of bioSiO_2 to dissolution, remineralization, and diagenetic

alteration, (e.g., Ragueneau et al., 2000) all contribute to the fact that at present there is no straightforward way to relate bioSiO_2 burial in deep time to variations in Si supply from continental weathering. As a consequence, our understanding of the silicate weathering thermostat operation under the extreme greenhouse climates of the early Paleogene, and especially its expression in siliceous sediments, is far from complete.

The modelled SWF (Caves et al., 2016) shows no straightforward correspondence to our ISS and PBS records. A peak in SWF appears to predate the peak in ISS occurrences by 1-2 myr, and there is no distinct feature in the SWF curve that could be confidently correlated with the PBS occurrences other than SWF deflection at ~45 Ma. Taken at face value, these discrepancies could be interpreted to reflect some kind of long-term decoupling of the Si and C cycles through the early Paleogene. Despite rapid rates of early SiO_2 diagenesis observed in laboratory experiments (e.g., Kastner et al., 1977), the present-day distribution of chert and porcellanite (Muttoni and Kent, 2007; Tatzel et al., 2015) suggests ISS formation lags the accumulation of the precursor sediment by several myrs. Also, as hypothesized above, early Paleogene PBS pool is most likely partially depleted due to ISS formation. Thus, the ISS and PBS records can only be considered a measure of geographic extent of a variety of siliceous facies and thus they do not necessarily evidence high rates of bioSiO_2 burial. Blake Nose bioSiO_2 concentration records (Witkowski et al., under review), however, are remarkably coherent with both the SWF model (Caves et al., 2016), and the ISS and PBS records presented here. This suggests that the discrepancies between the SWF curve (Caves et al., 2016) and the observations on biosiliceous sediments in the Atlantic Ocean result from model imperfections, incompleteness of the record due to extensive stratigraphic gaps (Aubry, 1995; Boyle et al., 2017; Witkowski et al., 2020), or both.

6.2. Western North Atlantic siliceous microfossil assemblages - the neritic paradox

The key finding of the present study is that P+E ISS and PBS occurrences are generally restricted to proximal sites, adjacent to continental margins (Fig. 1A-B; Fig. S1). Regardless of upwelling, which is generally linked to the eastern coasts of the oceans, continental margins are among the areas of the highest modern diatom production due to nutrient supply from terrestrial runoff (Malviya et al., 2016; Abrantes et al., 2016). Yet, siliceous production on continental margins, including neritic sites, is usually neglected in paleoceanographic studies. This is due to a number of reasons, including age control uncertainties (e.g., Oreshkina and Aleksandrova, 2007) and the scarcity of geochemical data (see discussion in Witkowski 2018). The present study emphasizes the need to reconsider the importance of marginal settings in the Paleogene bioSiO_2 production and burial. This is best represented in the Blake Nose siliceous microfossil assemblages

508 (Fig. 6), i.e., the only currently available single-locality record of bioSiO_2 accumulation through
509 almost the entire P+E period.

510 Witkowski et al. (2014) reported unusually high percentages of neritic diatoms from a
511 narrow interval spanning the MECO event in Holes 1051A and 1051B (~41.5 through 39.5 Ma).
512 High percentages of diatoms usually occurring in shelfal assemblages contrasted with the
513 hemipelagic to pelagic setting of the Blake Nose sites. Fontorbe et al. (2016) suggested that the
514 paleoecological assignments of Witkowski et al. (2014) may have been mistaken. Using data
515 included in the Neptune Database (NSB), Fontorbe et al. (2016) cited the occurrences of neritic
516 diatom genera at unquestionably pelagic sites, arguing for a habitat change over geological
517 timescales. Depending on the methodology of studies incorporated into NSB (Lazarus, 1994;
518 Renaudie et al., 2020), the database includes quantitative data only for some sites, and the prevalent
519 qualitative data may only indicate the presence or absence of a taxon in a given deep-sea hole.
520 Published diatom assemblage records testify to the contrary: since the Cretaceous, when diatoms
521 first proliferated in marine environments, taxa such as *Paralia* and *Pseudopodosira* are abundant in
522 near-shore environments (e.g., Barron et al., 1984; Witkowski et al., 2011), and sparse or absent in
523 the pelagic realm (e.g., Davies et al., 2006; Witkowski et al., 2012). This strongly suggests that
524 preference for habitat is a conservative trait in diatoms.

525 In the present study, in order to avoid interpreting diatom paleoecology based on poorly
526 understood entirely fossil taxa, we limit our analysis to *Paralia* and *Pseudopodosira*. High *Paralia*
527 + *Pseudopodosira* percentages are characteristic of the entire P+E siliceous microfossil record at
528 Blake Nose (Fig. 6C). Hence, we argue there is nothing unusual in sparse occurrences of neritic
529 diatoms in pelagic sediments: tycho planktic diatoms such as *Paralia* are known to be able to
530 survive suspension by wave action, and even though they have a global distribution, their primary
531 habitat is on sand grains within the littoral zone (Round et al., 1990, Gebühr et al., 2009). At Blake
532 Nose, however, neritic diatoms consistently make up ~66% of the diatom assemblage over the span
533 of ~30 million years. Calcareous nannofossil assemblages at Blake Nose sites also show high
534 proportion of braarudosphaerids (Newsam et al., 2017), indicating that enrichment in neritic
535 component is not confined to diatoms.

536 Fontorbe et al. (2016) also cited lack of evidence for large-scale reworking or downslope
537 movement of sediments draping Blake Nose. Although contribution from reworking and downslope
538 transport could not be ruled out, the interpretation of Witkowski et al. (2014) invoked lateral
539 currents as the medium responsible for the transport of neritic diatoms into the open ocean zone,
540 following observations by Martin (2003). Such lateral currents are generated by cyclonic eddies,
541 commonly observed in association with western boundary currents (Roughan et al., 2017). Along

542 today's Blake Plateau, frontal eddies forming on the landward side of the Gulf Stream not only
543 supply sub-thermocline nutrients to the continental shelf, but also provide an efficient means for
544 offshore export of neritic phytoplankton (Lee et al., 1991). One alternative explanation for such
545 high proportion of neritic diatoms in pelagic sediments could be preferential dissolution, which
546 leads to selective concentration of heavily-silicified diatoms by dissolution of more fragile forms
547 either at the sediment-water interface, or in transit through the water column (e.g., DeMaster, 2014).
548 Preferential dissolution should be expected to favor preservation of radiolarians over diatoms,
549 regardless of the degree of silicification. Yet, D:R ratios for the time period 62-61 Ma range as high
550 as 250, showing that the majority of bioSiO_2 preserved in sediments is of diatom origin (Hollis et al.,
551 1995; Renaudie et al., 2018). Low D:R ratios should be expected if the Blake Nose sediments were
552 enriched in radiolarians due to preferential dissolution.

553 In their interpretation of trends in biosiliceous production through the MECO event,
554 Witkowski et al. (2014) considered diatom production to be higher in the neritic rather than in the
555 pelagic zone of the western North Atlantic Ocean. This is consistent not only with actualistic
556 observations, generally indicating nutrient-rich continental margins and upwelling zones as the key
557 loci of diatom production, but also with fossil evidence from the eastern North American seaboard.
558 Unaltered Paleogene diatom-rich sediments are scarce along the Atlantic coast. However, Weaver
559 and Wise (1974), and Laws and Thayer (1992) presented compelling evidence for the diatomaceous
560 origin of opaline claystones that are widespread on the Atlantic coastal plain, especially from the
561 Tallahatta Fm. These sediments span calcareous nannofossil zones NP12-NP14 (Bybell and Gibson,
562 1985) (i.e., ~53.7 through 46.3 Ma relative to GTS2012, see Fig. 3B), and thus are approximately
563 correlative to peak ISS occurrence interval in the NW Atlantic. Further evidence for sustained high
564 diatom production along the Gulf of Mexico coast comes from Fayette County marine diatomite
565 exposures (Davis et al., 2016) that likely fall within nannofossil zone NP19-20 in the late Eocene
566 (~37 through ~34.4 Ma in GTS2012; Fig. 3B). Finally, several holes drilled on the New Jersey rise
567 and slope recovered shallow-water sediments that preserve late Eocene diatom-rich sediments (e.g.,
568 Sites 612, 904 and 1073; see Table S1).

569 The Blake Nose diatom record offers insights into the composition of biosiliceous sediments
570 preserved along the eastern margin of North America, and thus is an important supplement to the
571 compilation of geographic and temporal distribution of the Atlantic P+E ISS and PBS. Using our
572 siliceous microfossil data and published records from onshore and deep-sea sites, we argue that
573 high bioSiO_2 production at neritic sites is the key to understanding the ISS distribution in the
574 Atlantic Ocean. Such scenario of neritic diatom production exceeding diatom production rates in
575 the pelagic zone is consistent with actualistic models (Malviya et al., 2016; Abrantes et al., 2016),

but also with our current understanding of diatom evolution, with an invasion of pelagic environments only after the establishing of a successful neritic mode of life (Sims et al., 2006).

6.3. Implications for paleocirculation

One of the key questions surrounding the occurrence of early Paleogene ISS is why siliceous sediments tend to focus in the western North Atlantic. On one hand, the large concentration of siliceous facies could be an artifact related to the uneven geographic coverage of deep-sea sites (Fig. S1, see also Supplementary Text). On the other hand, however, paleogeographic maps (Fig. 7 and Fig. S3), and published records (e.g., Berger, 1970; Miskell et al., 1985; Moore et al., 2008; Fontorbe et al., 2016) suggest ocean circulation may have been an important control.

The P+E NW Atlantic bioSiO_2 accumulation belt (Fig. 7, Fig. S3) represents the most extensive and persistent zone of ISS and PBS occurrence examined here. The proto-Gulf Stream, which was likely in existence since the Jurassic (Gradstein and Sheridan, 1983; see also Pinet et al., 1981; Wade and Kroon, 2002) would have distributed dissolved SiO_2 supplied from continental weathering (Penman 2016; Penman et al. 2019), along with other nutrients, thus sustaining a high bioSiO_2 production zone along the eastern margin of North America. For the deep waters bathing the eastern margin of North America, Fontorbe et al. (2016) postulate a probable Southern Ocean or Tethyan source. This is consistent with our paleogeographic compilation (Fig. 7, Fig. S3), showing that the SiO_2 production and preservation zone generally propagated toward the NE, reaching a maximum extent by ~50 Ma, i.e., in the final phases of the EECO.

The NW Atlantic bioSiO_2 accumulation zone started to diminish between ~50 and 49 Ma (Fig. 7B, Fig. S3). Recent evidence suggests that at that time, subsidence of Greenland-Scotland Ridge enabled southwestward flow of young waters as a deep western boundary current (Hohbein et al., 2012). These water masses would have been highly SiO_2 -undersaturated and detrimental to bioSiO_2 preservation, thus promoting bioSiO_2 dissolution along their path in the western North Atlantic. This is consistent with the timing of ISS occurrences in Holes 1050A and 1051A, but also with sedimentological evidence from the Blake Nose region. The prominent silicified interval in Hole 1051A (Fig. 5) consists of winnowed foraminiferal packstone indicative of a vigorous bottom current (Norris, Kroon, et al., 1998). The timing of the Northern Component Water (NCW) export is debated (Via and Thomas, 2006; Boyle et al., 2017; Coxall et al., 2018; Hutchinson et al., 2019), but the spatial and temporal distributions of P+E ISS and PBS presented here strongly support an early flow of NCW as proposed by Hohbein et al. (2012). Thus, in a broader perspective, the widespread silicification of deep-sea sediments through the EECO may represent one of the aspects

of deep-sea erosion documented at a large number of Atlantic deep-sea sites (Aubry, 1995), and linked by Hohbein et al. (2012) with the onset of Judd Falls Drift deposition in the North Atlantic.

A final aspect to consider in the discussion of siliceous sediments in the western North Atlantic is mass wasting. There is ample evidence for slope failures in the western North Atlantic in the early Paleogene (Norris et al., 2001). Siliceous turbidites, often associated with ISS, have been documented at numerous sites in the Bermuda Rise region (e.g., Sites 6-7, Sites 384-387; see Riech and von Rad, 1979). Slope failures would have periodically distributed the bioSiO_2 -rich sediments originally draping the continental slope over a large area of the seabed underneath generally oligotrophic waters in the pelagic zone of the western North Atlantic. Also, redeposition by gravity currents into the deep basin would re-expose bioSiO_2 -rich sediments to SiO_2 -undersaturated bottom waters and thus promote further dissolution and reprecipitation as ISS.

7. Conclusions

The present study was initiated to test the hypothesis of Muttoni and Kent (2007), who proposed that the widespread early Paleogene chert and porcellanite formed via inorganic precipitation under oligotrophic conditions in the oceans. Based on the consistent geographic patterns in ISS and PBS distribution (including numerous co-occurrences, not considered in previous work), and the generally inverse relationship between ISS and PBS distribution through time, we argue for a biogenic origin of the P+E ISS. Depending on the depositional setting, the biogenic precursors to chert and porcellanite underwent silicification either through exposure to SiO_2 -undersaturated waters at the sediment-water interface, facilitated by the generally low sedimentation rates through the early Eocene, or – conversely – through elevated temperatures and pressures due to rapid burial.

Biogenic origin of the ISS precursors has been difficult to reconcile with evidence for generally oligotrophic conditions prevailing in the Atlantic Ocean through the EECO. We document persistent, high bioSiO_2 production on the North American shelf. Following Witkowski et al. (2014), we propose that offshore export, likely associated with Gulf Stream frontal eddies, was responsible for displacing neritic diatoms into the pelagic zone of the western North Atlantic Ocean. An early southward flow of nutrient-depleted NCW facilitated dissolution of bioSiO_2 -rich sediments along the North American continental margin. Thus, the prolonged supply of bioSiO_2 from the North American margin coupled with plate tectonic reorganization that resulted in changes to circulation patterns contributed to widespread silicification in lower Eocene sediments despite the prevailing oligotrophic surface water conditions. Even if this model does not apply to NE and S Atlantic ISS

642 occurrences, it does help explain why chert and porcellanite are so prolific in the Gulf of Mexico,
643 the Caribbean, and along the eastern North American margin.

644 Our study shows that the distribution of Early Cenozoic siliceous sediments in the Atlantic
645 Ocean was influenced by an interplay of tectonics, climate, ocean circulation, and bioSiO_2
646 production and diagenesis. The interpretation of early Paleogene siliceous sedimentation in the
647 Atlantic Ocean presented here is simpler than the model proposed by Muttoni and Kent (2007). It is
648 also consistent with micropaleontological evidence, well-established views on bioSiO_2 diagenesis
649 (e.g., Hesse, 1983; DeMaster, 2014; Frings, 2017), and finally - with the current understanding of
650 the ocean's biogeochemical evolution through the late Mesozoic and Cenozoic (Maldonado et al.,
651 1999; Fontorbe et al., 2016, Conley et al., 2017), which suggests that diatom proliferation
652 contributed to a global dissolved silicate drawdown before the K/Pg event, making precipitation of
653 SiO_2 from seawater highly unlikely.

654

655 **Acknowledgements**

656 This study was supported by grant no. 2014/13/B/ST10/02988, awarded by the National Science
657 Centre (Poland). Kevin McCartney and Jörn Thiede are thanked for kindly donating their sets of
658 DSDP and ODP volumes to the Institute of Marine and Environmental Sciences at University of
659 Szczecin, which greatly facilitated this work. We gratefully acknowledge the detailed comments by
660 the editor Thomas Algeo, and insightful reviews by Johan Renaudie and one anonymous reviewer.

907 **Figure captions**

- 908 **1.** Lower Paleocene through upper Eocene indurated siliceous sediment (A) versus preserved
909 biosiliceous sediment (B) occurrences plotted on a 10° latitude × 10° longitude grid.
910
- 911 **2.** Range charts showing the occurrences of lower Paleocene through upper Eocene indurated
912 siliceous sediments (ISS) versus preserved siliceous sediments (PBS) in the Atlantic Ocean
913 deep-sea holes in 1 million year (myr) time bins. Study sites are grouped according to the major
914 sub-basins: Caribbean, Gulf of Mexico, and South Atlantic (A), NE Atlantic (B) and NW
915 Atlantic (C).
916
- 917 **3.** Secular distribution of lower Paleocene through upper Eocene indurated siliceous sediment
918 (ISS) (A) and preserved biosiliceous sediment (PBS) (B) occurrences in the Atlantic Ocean
919 plotted versus published silicate weathering flux (SWF) curve (C) and benthic foraminiferal
920 carbon and oxygen stable isotope records (D). Grey areas in ISS and PBS plots denote the
921 difference between the number of sites with reliable age control and approximate age control in
922 each 1-myr time bin. Schematic representation of climatic trends through the early Paleogene is
923 consistent with Cramwinckel et al. (2018). SWF data from Caves et al. (2016). $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$
924 data from Cramer et al. (2009; readjusted to GTS2012). Approximate ranges of onshore diatom-
925 bearing stratigraphic units provided in panel B are discussed in text.
926
- 927 **4.** Regression plots for indurated siliceous sediments (ISS) and preserved biosiliceous sediments
928 (PBS) against published $\delta^{18}\text{O}$ (A-B), $\delta^{13}\text{C}$ (C-D) from Cramer et al. (2009), and against silicate
929 weathering flux (SWF) (E-F) from Caves et al. (2016).
930
- 931 **5.** BioSiO_2 concentrations (weight per cent, wt%) plotted against linear sedimentation rates (LSR),
932 generalized lithology, and indurated siliceous sediment (ISS) occurrences at selected western
933 North Atlantic sites through the early Paleocene to late Eocene period. Roman numerals refer to
934 lithological units distinguished in the relevant site reports (see Table S16 in the online
935 Supplementary Materials for a complete list of references). BioSiO_2 concentrations and LSR data
936 from Witkowski et al. (under review).
937
- 938 **6.** Siliceous microfossil assemblage records through the early Paleocene through late Eocene
939 period at ODP Holes 1050A,C, 1051A, and 1053A. (A) Variations in Total Siliceous
940 Microfossil (TSM) abundance. (B) Diatom:radiolarian ratios. (C) Relative abundance of neritic

diatoms, based on *Paralia* spp. and *Pseudopodosira* spp. (D) Relative abundance of pelagic diatoms, exemplified by *Hemiaulus* spp. (E) Relative abundance of diatom resting spores. (F) Schematic representation of climatic trends through the early Paleogene is consistent with Cramwinckel et al. (2018).

7. Paleogeographic shifts in siliceous sediment occurrences in the Atlantic Ocean for the late Paleocene (A), peak ISS frequency (B), peak PBS frequency (C), and before the Eocene-Oligocene Transition (D). For a complete set of paleogeographic maps see Fig. S3 in the online Supplementary Materials. Base maps plotted using Ocean Drilling Stratigraphic Network Advanced Plate Tectonic Reconstruction application.
