13 **ABSTRACT**

14 The infection of a bacterium by a phage starts with attachment to a receptor molecule
15 on the host cell surface by the phage. As receptor-phage interactions are crucial to
16 successful infections, they are major determinants of phage host-range and by
17 extension of the broader effects that phages have on bacterial communities. Many
18 receptor molecules, particularly membrane proteins, are difficult to isolate because
19 their stability is supported by their native membrane environments. Styrene maleic
20 acid lipid particles (SMALPs), a recent advance in membrane protein studies, are the
21 result of membrane solubilizations by styrene maleic acid (SMA) co-polymer chains.
22 SMALPs thereby allow for isolation of membrane proteins while maintaining their
23 native environment. Here, we explore SMALPs as a tool to isolate and study phage-
24 receptor interactions. We show that SMALPs produced from taxonomically distant
25 bacterial membranes allow for receptor-specific decrease of viable phage counts of
26 several model phages that span the three largest phage families. After characterizing
27 the effects of incubation time and SMALP concentration on the activity of three
28 distinct phages, we present evidence that the interaction between two model phages
29 and SMALPs is specific to bacterial species and the phage receptor molecule. These
30 interactions additionally lead to DNA ejection by nearly all particles at high phage
31 titers. We conclude that SMALPs are a potentially highly useful tool for phage host-
32 interaction studies.

33

34 **IMPORTANCE**

35 Bacteriophages (viruses that infect bacteria or phages) impact every microbial
36 community. All phage infections start with the binding of the viral particle to a specific
37 receptor molecule on the host cell surface. Due to its importance in phage infections,
38 this first step is of interest to many phage-related research and applications.
39 However, many phage receptors are difficult to isolate. Styrene maleic acid lipid
40 particles (SMALPs) are a recently developed approach to isolate membrane proteins
41 in their native environment. In this study we explore SMALPs as a tool to study
42 phage-receptor interactions. We find that different phage species bind to SMALPs,
43 while maintaining specificity to their receptor. We then characterize the time and
44 concentration dependence of phage-SMALP interactions, and furthermore show that
45 they lead to genome ejection by the phage. Combined, the results presented here
46 show that SMALPs are a useful tool for future studies of phage-receptor interactions.

47

48 **INTRODUCTION**

49 The first stage of infection by a bacteriophage consists of the viral particle binding to
50 a cognate receptor on the host cell surface (1, 2). Each phage attaches to a specific
51 receptor molecule, and as a result largely determine the specificity to hosts that is
52 common among characterized phages (3, 4). Indeed, specificity of phages to their
53 receptors is a useful tool for characterizing bacterial strains (5). In addition to phage
54 applications, the molecules involved in phage-receptor interactions are often
55 evolutionary hotspots due to their crucial role in successful infections (6, 7). As such,
56 understanding phage-receptor interactions is important for understanding the
57 evolutionary dynamics that govern networks of phages and hosts (8) and the role that
58 phages play in regulating bacterial communities (9–11). Indeed, phage-receptor
59 binding is a widely investigated research theme, and studies of phage-receptor
60 interactions have among others ranged from the mechanics of phage binding and
61 DNA ejection (12–14) to the structural modelling of bound receptor molecules (15,
62 16).

63 Known phage receptors include a wide variety of diverse molecules on the
64 bacterial cell surface (2, 17). While some phages bind to pili, flagella, or cell
65 capsules, many phage receptors are associated with the bacterial cell envelope (17).
66 Which molecules serve as receptor molecules largely depends on the diversity of
67 bacterial cell wall structures (18). Known receptors in Gram-positive bacteria are

68 mostly present in the peptidoglycan layer (2, 18), while those in Gram-negative
69 bacteria include sugar moieties in lipopolysaccharide (LPS) chains and membrane-
70 incorporated porin and transport proteins (2, 17). Due to their association with the cell
71 membrane, phage receptors, especially membrane proteins, can be challenging to
72 study. Proteinaceous phage receptors are generally incorporated into the bacterial
73 cell membrane and are thereby dependent on this membrane to maintain correct
74 folding (19), which makes them notoriously difficult to isolate (20, 21). This limits the
75 number of phages of which the interaction with a receptor can be studied in detail.

76 Among novel solutions to facilitate membrane protein studies is styrene maleic
77 acid (SMA) (22). SMA is an amphipathic co-polymer composed of chains with
78 alternating hydrophobic styrene and hydrophilic maleic acid groups (23). Upon
79 addition of SMA to lipid bilayers, it incorporates itself into the membrane, which leads
80 to the solubilization of membranes into styrene maleic acid lipid particles (SMALPs,
81 Figure 1a) (22). In SMALPs, the SMA polymer is wound around a disk of membrane
82 about 10 nm in diameter, with hydrophobic styrene groups intercalated between lipid
83 tail acyl groups and hydrophilic maleic acid groups pointed outward (23). Membrane
84 proteins may be captured within the confines of SMALP discs, and SMALPs thus
85 allow isolation of bacterial membrane proteins while maintaining their natural lipid
86 environment. Since their initial development for membrane protein studies, SMALPs
87 have been used to obtain three dimensional structures of membrane proteins (24,
88 25), and obtain their biophysical characteristics (22, 26). As SMALPs are useful
89 agents for bacterial membrane isolation, they are also potentially useful for phage-
90 receptor studies.

91 In this study, we report on the exploration of SMALPs as a platform to study
92 phage-host interactions. We test whether SMALPs can inhibit phages that infect
93 taxonomically diverse bacteria by binding to diverse membrane-associated receptor
94 molecules. We then show that phages interacting with SMALPs maintain specificity
95 to their receptors, and that they eject their DNA after binding to SMALPs.

96

97 **RESULTS & DISCUSSION**

98 **SMALP formation in two taxonomically distant bacteria.** While SMALPs have
99 been developed as a platform to study membrane proteins for over a decade (27),
100 this has mostly focused on *Escherichia coli* membranes. It is consequently unknown
101 whether differences in membrane composition and cell wall structure between

102 bacterial lineages (28) will lead to differences in membrane solubilization by
103 SMALPs. To test this, we started by solubilizing membranes of two taxonomically
104 distant bacteria, one Gram-positive and one Gram-negative, with styrene maleic acid
105 co-polymer. As sample bacteria, we selected *E. coli* and *Bacillus subtilis*. Membrane
106 solubilization of these bacteria, evidenced by diminishing absorbance at 600 nm
107 upon SMA addition, showed similar rates of SMALP formation in the two bacterial
108 membranes (Figure 1b). Dynamic light scattering (DLS) revealed that the Gram-
109 negative *E. coli* membranes formed uniform particles of roughly 10 nm in diameter,
110 as is normally observed for SMALPs (Figure 1c) (22). Interestingly, DLS of Gram-
111 positive *B. subtilis* SMALPs showed larger particles of 50-100 nm (Figure 1c).
112 Previous studies reported that SMALP size is dependent on the ratio between polar
113 and apolar groups in the SMA polymer (29) and the ratio between polymer and
114 membrane (30, 31). While no extant studies report on the effects of membrane
115 composition from different bacteria on SMALP size, distinct lipid composition of *E.*
116 *coli* and *B. subtilis* membranes (32) may lead to differences in SMALP sizes as we
117 observed. Beyond lipid composition, the 40 nm thick outer peptidoglycan layer (33)
118 that is attached to the outer membrane of *B. subtilis* by lipoteichoic acids makes cell
119 envelopes much thicker than those of *E. coli* (34). Since DLS measurements assume
120 a spherical object, this could further contribute to the larger apparent diameter of *B.*
121 *subtilis* SMALP.

122

123 **SMALPs decrease viable phage counts.** Next, we tested whether SMALPs from
124 both Gram-positive *B. subtilis* and Gram-negative *E. coli* bacteria inhibit the lytic
125 activity of three model phages (Table 1). As model phages we selected one member
126 from each of the three major International Committee on the Taxonomy of Viruses
127 (ICTV)-recognized families of tailed phages (*Myo*-, *Podo*- and *Siphoviridae*) (35, 36),
128 as the distinct morphologies of these families differentiates their binding mechanisms
129 (1). The three model phages, *Podoviridae Bacillus* phage ϕ 29, *Siphoviridae*
130 *Escherichia* phage λ and *Myoviridae Escherichia* phage T4, each bind to distinct
131 receptor molecules. *Bacillus* phage ϕ 29, like many phages infecting Gram-positive
132 bacteria (18), binds to cell wall teichoic acids. *Escherichia* phage λ exclusively binds
133 to a maltose porin protein LamB, while *Escherichia* phage T4 binds to both outer
134 membrane protein C (OmpC) and glucose moieties in lipopolysaccharide (LPS)
135 chains. While some phages bind to other structures than our model phages, most

136 notably pili and flagella (1), the use of SMALPs to study phage-host interactions will
137 evidently have to focus on membrane-associated structures. Our model phages
138 additionally allowed us to test whether beside proteins, LPS and peptidoglycan layers
139 attached to SMALPs are available to phages.

140

141 As preliminary examination of phage binding by SMALPs, we tested phage lytic
142 capability in liquid cultures after treatment with SMALPs prepared from 10 mg/ml
143 bacterial membrane. Addition of SMALPs to liquid bacterial cultures infected with
144 phage at titers of 10^4 to 10^6 pfu/ml phage (starting multiplicity of infection: 10^{-4} to 10^{-2} ,
145 Figure 2a) resulted in complete inhibition of phage lytic activity. Differences in the
146 titer at which we observed complete inhibition of phage lysis suggested varying
147 sensitivities to SMALPs among the three phages. Because these phages differ
148 greatly in infection dynamics (e.g. burst sizes from 100-1000) (37–39), and because
149 liquid assays are nonquantitative (40), we next quantified SMALP-phage interactions
150 through plaque counts after SMALP treatment. Viable phage counts at different time
151 intervals revealed that 1 to 0.1% of 10^6 pfu/ml solutions remained after five minutes
152 of incubation with SMALPs (Figure 2b). Longer incubations showed a slower rate of
153 decrease in viable phage populations, especially for T4 and $\phi 29$, while after 20
154 minutes decreases in viable phage counts largely plateaued. SMALP-phage
155 interactions thus seem to proceed in a two stage process, with a rapid initial phase
156 followed by a slowed secondary phase, similar to the two-stage adsorption dynamics
157 that are characteristic of phages binding to live host cells (41).

158 In addition to time-dependent dynamics, we measured the decrease in viable
159 phages upon addition of different concentrations of SMALPs (Figure S1). Undiluted
160 SMALP stocks used in these experiments had been prepared from 10 mg/ml
161 membrane suspensions and 20 mg/ml SMA, but as some of these materials are
162 removed in the SMALP production process, these values do not accurately represent
163 SMALP concentrations. Hence, in the following experiments dilution factor was used
164 instead of concentration counts. Experiments with increasingly diluted SMALPs
165 confirmed that a positive relationship existed between SMALP concentration and
166 phage inhibition. Of the three model phages, $\phi 29$ was most sensitive to SMALPs, as
167 10,000 times diluted SMALP stocks still inhibited about 90% of a 10^6 pfu/ml phage
168 $\phi 29$ solution. As $\phi 29$ binds to teichoic acids on the *B. subtilis* cell surface, its
169 sensitivity to SMALPs indicates that the lipoteichoic acid linkages between

170 membrane and peptidoglycan layers (42) are maintained in the *B. subtilis* SMALP
171 solutions. Phages λ and T4 exhibited lower sensitivity to SMALPs than ϕ 29, with
172 SMALP dilutions of a 1,000-fold or more having little effect on phage populations.
173 While at high SMALP dilutions the behavior of these phages is similar, at low
174 dilutions T4 is about two orders of magnitude less sensitive than λ . This likely reflects
175 their disparate binding dynamics, as λ engages in a single interaction with a LamB
176 protein (43) whereas T4 requires up to four independent interactions of tail fibers to
177 receptors for successful infection (44). It is likely that each T4 phage binds to a
178 separate SMALP particle. This difference in the number of receptor interactions per
179 phage particle suggests that T4 would need to bind fourfold more SMALPs to yield a
180 similar decrease in the number of viable phages. Equal SMALP amounts will
181 therefore bind more λ than T4 particles, leading to lower inhibition for T4 than for λ .
182 Meanwhile, the fact that ϕ 29 exhibits the highest sensitivity to SMALPs implies that
183 teichoic acids are present in SMALPs. Teichoic acids are present in larger numbers
184 in the cell wall than protein receptors such as LamB and OmpC, to which λ and T4
185 bind. This higher abundance of ϕ 29 receptors increases the number of binding
186 events for ϕ 29 and thus decrease of viable phage counts. Together, these results
187 show that for three distinct phages that infect two taxonomically distant hosts,
188 SMALPs are a potential platform for the study of phage-receptor.

189
190 **SMALPs cause receptor-specific genome ejection by phages.** To test whether
191 phage-SMALP interactions led to DNA ejection, we measured fluorescence of DNA-
192 specific fluorophores before and after incubation with SMALPs. This experiment
193 employed the YO-PRO DNA stain, which was earlier shown to bind free DNA at a
194 much faster rate than encapsulated phage DNA (45). Additionally, this dye has been
195 used to study DNA ejection in *Salmonella* phage P22 (46). We first tested our
196 experimental setup by comparing fluorescence signal of λ phage stocks, *E. coli*
197 SMALPs, and a combination of the two (Figure 3a). This revealed that SMALP stocks
198 have sizeable fluorescence intensity when added to YO-PRO DNA stain.
199 Fluorescence measurements of separate polymer confirmed that SMA itself interacts
200 with the DNA stain. This non-specific interaction with DNA stain likely results from the
201 strong overall negative charge of the SMA polymer (47) making it similar to DNA.
202 Despite this high background fluorescence signal, when we incubated SMALPs with
203 phages, fluorescence significantly increased (two-tailed t-test, $p = 0.0007$, Figure 3a).

204 Since the fluorescence of phage stocks was negligible, the increase evidently results
205 from an increase of free DNA. Similar methods with the same DNA stain previously
206 showed that fluorescence increase in *Salmonella* phage P22 in the presence of
207 purified LPS is due to an increase in free DNA after being ejected by phage
208 particles¹¹. We therefore concluded that phage λ ejected its DNA in the presence of
209 *E. coli* SMALPs.

210 Next, we examined whether phage DNA ejection was specific to SMALPs
211 prepared using the appropriate host, we incubated phages λ and ϕ 29 with SMALPs
212 prepared from either *E. coli* or *B. subtilis*. After subtracting background signal from
213 SMALP-only and phage-only samples, phage λ added to *E. coli* SMALPs had a
214 significantly higher fluorescent signal than phage ϕ 29 added to the same SMALPs
215 (two-tailed t-test, $p = 0.03$, Figure 3b). Incubation of the two phages with SMALPs
216 prepared from *B. subtilis* resulted in the reverse, with significantly higher background-
217 adjusted fluorescence for phage ϕ 29 (two-tailed t-test, $p = 0.02$, Figure 3c). From
218 these results, we concluded that both phage λ and ϕ 29 ejected their genomes in the
219 presence of SMALPs prepared from their cognate hosts. Additionally, we concluded
220 that SMALP-phage interactions reflect specific phage-host interactions, at least at
221 this large phylogenetic distance (*E. coli* and *B. subtilis* are from different bacterial
222 phyla and have different Gram stains).

223 We further determined the extent of specificity by comparing phage λ DNA
224 ejection when added to SMALPs prepared from *E. coli* K-12 and *E. coli* Δ LamB. For
225 these tests we employed a Qubit fluorometer, which is a calibrated system for DNA
226 quantification. In three repeats of experiments that were each composed of biological
227 triplicates, background-adjusted DNA measures were consistently higher when we
228 added phage λ to *E. coli* K-12 SMALPs than to *E. coli* Δ LamB SMALPs (two-tailed t-
229 test, $p = 6 \cdot 10^{-6}$, Figure 3d). Assuming that background-adjusted values were
230 accurate representations of free DNA amounts, we estimated the fraction of phages
231 which had ejected their DNA. Based on the stock phage titer of $1 \cdot 10^{10}$ pfu/ml and a
232 molecular weight of $1.5 \cdot 10^7$ g/mol for λ DNA, the theoretical maximum of ejected
233 DNA in our reaction was 0.80 ng/ μ l. The calibrated measurements identified $1.09 \pm$
234 0.28 ng/ μ l DNA in the reactions. Assuming a slight underestimation (i.e. well within
235 an order of magnitude) of the added phage stock, these results indicated that (nearly)
236 all phage particles ejected their genome. The SMALP-phage interaction is thus highly
237 efficient at prompting DNA ejection in phage λ . Combined, these fluorescence-based

238 experiments provided ample evidence that DNA ejection in SMALP-phage
239 interactions is receptor specific. SMALPs could therefore be a powerful tool in
240 studying phage-receptor interactions, especially for phages that interact with
241 membrane proteins.

242

243 **SMALPs as tool to study phage-host interactions.** While the above results show
244 SMALPs are useful tools to study phage-host interactions, there are also potential
245 drawbacks to consider. For example, SMALPs are strong chelators of divalent
246 cations (22). This may be particularly problematic in phage-host studies, as some
247 phages are dependent on Mg^{2+} or other divalent cations for successful infection
248 initiation (48, 49). Due to their chelating activity, proteins that are active against DNA,
249 like polymerases, nucleases, or restriction enzymes, may not be active in the
250 presence of SMALPs. Indeed, when we tested the activity of DNase in the presence
251 of SMALPs, we observed inhibition of nuclease activity (Figure 4a). This additionally
252 supported the above findings that SMALPs bind to DNA-specific fluorophores, as
253 they form thick smears at low molecular weight when subjected to agarose gel
254 electrophoresis. Similarly, amplification reactions using *Taq* polymerase were entirely
255 inhibited by SMALPs (Figure 4b). To circumvent this, we developed a method of
256 removing SMALPs from solution. This method is based on their chelating activity,
257 which leads to SMALP precipitation (22). Addition of calcium or magnesium to
258 SMALP solutions above 10 mM successfully removed almost all polymer from
259 solution (Figure 4c). However, SMALPs removal in this fashion could in turn inhibit
260 polymerases, as high concentration of divalent cations are known to do (50, 51).
261 Calcium particularly inhibits polymerases by outcompeting magnesium as co-factor
262 (51), although high magnesium concentrations also inhibit polymerases (50, 52).
263 Additionally, DNA molecules also interact with divalent cations (53), which should be
264 taken into account for further studies of DNA released by phages in the presence of
265 SMALPs. Applications of SMALPs to study phage-host interactions needs further
266 development of alternative means of SMALP removal. Alternatively, several modified
267 SMA polymers that are more positively charged and therefore potentially weaker
268 chelators have recently been developed (54–56). Their adoption for SMALP-phage
269 studies may lift the above described drawbacks.

270

271 **CONCLUSION**

272 In this study, we report on the potential utility of SMALPs for studies of
273 bacteriophage-receptor interactions. We found that SMALPs are viable tools,
274 because their interactions with model phage particles result in host- and receptor-
275 specific ejection of phage genomic material. As a result of our findings, SMALPs may
276 see adaptation as a platform to study various aspects of phage-receptor interactions.
277 SMALPs may be useful tool for cryo-electron microscopy of phages binding
278 mechanisms (15, 57–59), as this is implausible when using whole cells due to their
279 size (60). The differences in phage binding to 10 nm diameter SMALPs and to large
280 bacteria, across the surface of which phages often engage in 2D diffusion (1), might
281 further reveal details of the mechanics by which phages find their receptors.
282 Additionally, affinity purification or pulldown assays of phage bound SMALPs coupled
283 with mass spectrometry approaches may aid in receptor identification. While there
284 are drawbacks associated with SMALPs (i.e. their chelation of magnesium), further
285 developments of SMALPs as tools to study bacterial membrane proteins may aid in
286 their future applications in studying phage-receptor interactions.

287

288 **MATERIALS AND METHODS**

289 **Bacterial and bacteriophage strains.** To test whether bacterial membranes from
290 different bacteria could be solubilized by the SMA polymer, we used *E. coli* K-12
291 BW25113 (DSMZ #27469) and *Bacillus subtilis* 110NA (DSMZ #5547). To test
292 specificity of phages to SMALPs, we further used *E. coli* strains JW3996-1 (Δ LamB),
293 JW3596 (Δ RfaC), and JW2203 (Δ OmpC) from the Keio strain collection (61). The
294 phages used in this study were a virulent mutant of *Escherichia* phage λ obtained
295 from the Westerdijk Fungal Biodiversity Institute (62, 63), *Bacillus* phage ϕ 29 (DSMZ
296 #5546) and *Escherichia* phage T4 (DSMZ #103876). All chemicals were obtained
297 from Sigma Aldrich, except where stated otherwise.

298

299 **Bacterial cultivation and phage production.** Bacteria were cultivated in Lysogeny
300 Broth (LB) at 37°C under agitation at 180 rpm. Production of phage stocks was
301 according to the soft-agar overlay method as described before (64). Phage stocks
302 were kept at 4°C until further use. To enumerate phages, 0.1 ml exponentially
303 growing bacterial culture was added to 5 mL 0.7% (w/v) LB agarose (Bio-Rad), which
304 was subsequently layered on a 1.5% (w/v) LB agar plate. After the top layer had

305 dried, 10 μ l of 10-fold dilution ranges of phage stocks in SM buffer (100 mM NaCl, 8
306 mM MgSO₄ x 7 H₂O, 50 mM Tris-HCl pH 7.5) were pipetted on the agar. The plates
307 were placed at a 45° angle and until the phage dilutions had dried and then incubated
308 overnight at 37°C).

309

310 **Styrene Maleic anhydride co-polymer hydrolyzation.** Styrene maleic anhydride
311 co-polymer (67:33 ratio, SManh) (Polyscience) was hydrolyzed to styrene maleic acid
312 co-polymer as described before (22). In short, 12.5 g of SManh was suspended in a
313 round bottom flask containing 250 ml 1M NaOH. This flask was connected to a reflux
314 setup and the suspension was heated in sunflower oil at 98°C for 4 hours under
315 constant stirring. Afterward, the suspension was cooled to room temperature and 6 M
316 HCl was added to a final concentration of 1.1 M to precipitate the hydrolyzed
317 polymer. Styrene maleic acid (SMA) was pelleted by centrifugation at 7000 x *g* for 20
318 minutes, after which the supernatant was discarded. The pellet was resuspended in
319 250 mL 100 mM HCl and centrifuged at 7000 x *g* for 20 minutes, after which the
320 supernatant was discarded. This was repeated twice, once with 250 mL 100 mM HCl
321 and once with deionized water. The SMA pellet was frozen at -80°C and extensively
322 freeze dried. SMA was dissolved at a concentration of 60 mg/ml in 20 mM Tris-HCl
323 (pH 8) and stored at -20°C until further use.

324

325 **Bacterial membrane isolation and SMALP production.** To isolate bacterial cell
326 membranes, bacteria were first grown overnight at 37°C while shaking. Cells were
327 pelleted by centrifugation at 10,000 x *g*, 4°C for 15 minutes, after which supernatant
328 was discarded. Pellets were washed with the original volume of lysis buffer (50 mM
329 Tris HCl pH 7.5, 2 mM MgCl₂), after which centrifugation was repeated. After
330 discarding the supernatant, cells were re-suspended in 4 volumes of lysis buffer per
331 gram wet cell weight, to which 1 tablet of cComplete EDTA-free protease inhibitor was
332 added. To lyse the cells, the suspension was thrice passing through a model CF1
333 Cell Disruptor (Constant Systems) at 1.5 kBar. Cell debris was pelleted by
334 centrifugation at 12,000 x *g*, 4°C for 15 minutes and collecting the supernatant. Next,
335 membranes were pelleted by centrifuging the supernatants at 225,000 x *g*, 4°C for 1
336 hour. Pellets were re-suspended in lysis buffer and centrifuged again. Soluble
337 proteins were removed by resuspending the pellet in 200 mM NaCl + 20 mM Tris
338 HCl, pH 7.5 and repeating centrifugation. Pellets were dissolved in 20 mM Tris HCl

339 pH 7.5 + 200 mM NaCl at a concentration of 10 mg/ml and stored at -20°C until
340 further use.

341 To produce SMALPs from bacterial membranes, we suspended membranes in
342 200 mM NaCl + 20 mM Tris HCl, pH 7.5 and added SMA to obtain a final solution
343 with 10 mg/ml membrane and 20 mg/ml SMA (or a membrane:polymer ratio of 1:2).
344 To allow SMALP formation, solutions were incubated under constant rotation for 20
345 minutes at room temperature. Non-solubilized membrane material and excess SMA
346 were removed by filtration through a sterile 20 µm filter and extensive dialyzing
347 against 20 mM Tris HCl pH 7.5. SMALP solutions were stored at 4°C until further
348 use.

349 The effects of divalent cations on the SMA polymer were examined using
350 CaCl₂ and MgSO₄. To 14 mg/ml SMA polymer, 0-30 mM CaCl₂ or MgSO₄ were
351 added, and the OD_{259 nm} was measured in a cuvette using a NanoPhotometer C40
352 (Implen). The concentration of SMA in every sample was calculated using a linear
353 standard curve ranging from 0-40 mg/ml SMA.

354 To determine SMALP sizes, we used dynamic light scattering using a
355 Zetasizer ZS instrument (Malvern), using default software settings and multiple
356 narrow modes analysis of the correlation data. Before measurement, samples were
357 briefly degassed and equilibrated for 300 s at room temperature.

358 To test the efficacy of SMALP dissolution for different bacterial membranes,
359 membrane suspensions of 10 mg/ml were prepared in 200 mM NaCl + 20 mM Tris
360 HCl, pH 7.5 in 1.5 ml cuvettes. Subsequently, SMA was added to a final
361 concentration of 20 mg/ml and the OD_{600 nm} was followed over time in a
362 NanoPhotometer C40 (Implen), with measurements every 10 s.

363

364 **Effect of SMALPs on phage lytic activity.** Equal volumes of SMALP solution and
365 phage stock at 10-fold dilutions between 10¹ and 10¹⁰ pfu/ml were mixed and
366 incubated for 20 minutes at room temperature to allow phages to bind SMALPs.
367 SMALP and phage dilutions were prepared in sterile dilution buffer (100 mM NaCl +
368 50 mM Tris HCl pH 7.5) where necessary. Bacteria were grown to an OD_{600 nm} of 0.5
369 and 10 µl bacterial suspension was diluted in 89 µl fresh LB medium in a 96 wells
370 plate. Diluted bacteria were incubated at 37°C under agitation for 30 minutes, after
371 which 1 µl of SMALP/phage suspension was added. To bacteria-only controls, 1 µl
372 dilution buffer was added instead. The 96-wells plate was then incubated in a

373 Synergy H1 microplate reader (Biotek) at 37°C under continuous double orbital
374 shaking for 10 hours, during which the OD_{600 nm} was determined every 10 minutes.

375

376 **Characterizing SMALP-phage interaction with agar plate assays.** To determine
377 the effect of incubation length on SMALP-phage interactions, equal volume of phage
378 (at 10⁶ pfu/ml) and SMALP solutions were mixed. At five-minute time intervals
379 between 0 and 40 minutes, 20 µl aliquots were retrieved, to which CaCl₂ was added
380 to a final concentration of 20 mM. As negative control to establish original viable
381 phage counts, phage stock at 10⁶ pfu/ml was diluted in an equal volume of 200 mM
382 NaCl + 20 mM Tris HCl, pH 7.5, to which CaCl₂ was added to a final concentration of
383 20 mM. After a two-minute centrifugation at 21,000 x g, the supernatant was
384 retrieved and used to enumerate viable phage particles as described under “Bacterial
385 cultivation and phage production”. To test the effect of SMALP concentration on
386 phage inhibition, 10-fold SMALP dilutions were made in 100 mM NaCl + 50 mM Tris
387 HCl pH 7.5. Samples were subsequently prepared and enumerated in similar fashion
388 as in the time trials, except that only incubation times of 20 minutes were used.
389 Negative controls were produced in the same manner as for the time trials.
390 Decreases in viable phage particles were calculated by dividing phage titers after the
391 reaction by those obtained from negative controls. For both time trial and SMALP
392 concentration experiments, all samples consisted of biological triplicates.

393

394 **Spot assays to determine specificity.** SMALP and phage reactions, as well as
395 negative controls were performed as described in the previous section, with
396 incubation times of 20 minutes. After incubation, 10 µl spots of reaction mixture were
397 placed on top of a double layer agar plate prepared as described under “Bacterial
398 cultivation and phage production”. Spots were dried at room temperature and
399 subsequently incubated for 16 hours at 37°C.

400

401 **Transmission electron microscopy.** Before transmission electron microscopy,
402 phage stocks were purified using a preformed CsCl density gradient. A two-step
403 gradient was prepared in thin walled ultracentrifuge tubes (Beckman Coulter) using
404 CsCl at densities of 1.6 g/ml and 1.4 g/ml. On top of these layers, 1 ml 10¹¹ phage
405 preparation was placed, and density gradients were centrifuged at 111,000 x g for 2
406 hours using a Sw60Ti swinging bucket rotor (Beckman Coulter). After centrifugation,

407 white phage layers were collected by puncturing the tubes with a hypodermic needle,
408 as was advised before (65). To remove excess CsCl, phages were cleaned by three
409 consecutive washes with SM-buffer in an Amicon 30 kDa spin filter (Merck), which
410 was centrifuged for 10 minutes at 3,000 x *g*. Samples with SMALPs were then
411 prepared as described under “Characterizing SMALP-phage interaction with agar
412 plate assays” with an incubation time of 20 minutes and phage titers of 10¹⁰ pfu/ml.
413 Samples were applied to thin carbon-coated 400 square mesh copper grids (Electron
414 Microscopy Sciences), which were ionized by glow discharged 90 seconds. On top of
415 the grids, 3 µl sample were carefully pipetted and incubated at room temperature for
416 1 minute. Liquid was removed using filter paper (Whatman). Grids were then washed
417 thrice with 10 µl milli-Q water, each time removing liquid with filter paper. Finally, 3 µl
418 2% uranyl acetate was pipetted on the grids. After a final 30 s incubation at room
419 temperatures, uranyl acetate was removed with filter paper. TEM imaging used a
420 Philips CM200 (200 kV), while micrographs were captured using a TemCam- F416 4
421 kD (TVIPS) at 150,000x magnification using EM-MENU software.

422

423 **Fluorescence DNA ejection assays.** The first fluorescence assay tested DNA
424 ejection with *Escherichia* phage λ and SMALPs prepared from *E. coli* K12 BW25113
425 membranes. Phage stock was diluted to 10⁶ pfu/ml using SM buffer. Phage stock,
426 SMALP stock, and the two combined were incubated with 1.1 µM YO-PRO-1 iodine
427 (491/509, Invitrogen) for 20 minutes at 37°C, as described before for P22 and *S.*
428 *enterica* LPS (46). Fluorescence was then measured using a QuBit 4 fluorometer
429 (ThermoFisher), which used an excitation wavelength of 430-495 nm and measured
430 emission at 510-580 nm. Samples were composed of biological triplicates. To
431 determine specificity, *Escherichia* phage λ, *Bacillus* phage φ29, *E. coli* K12 BW25113
432 SMALPs, and *B. subtilis* 110NA SMALPs were measured separately and in every
433 possible combination of phage and SMALP in the same way.

434 For further quantification of DNA ejection after SMALP concentration, the
435 assay was repeated with 1·10¹⁰ pfu/ml *Escherichia* phage λ, and SMALPs from *E.*
436 *coli* K12 BW25113 and ΔLamB, using a dsDNA HS assay kit and Qubit fluorometer
437 (Thermo Fisher Scientific). This assay consisted of three repeats, with each repeat
438 consisting of biological triplicates. We calculated the theoretical amount of DNA that
439 was present in the phages in the sample using:

$$[\text{DNA}] = \frac{M_{\text{DNA}}}{A} \cdot 10^6[\varphi]$$

440 Where [DNA] is the DNA concentration in ng/ μ l, M_{DNA} is the molecular weight of λ
441 DNA ($1.5 \cdot 10^7$ pfu/ml), A is Avogadro's number, and φ is the phage titer in the
442 reaction ($3.2 \cdot 10^{10}$ pfu/ml).

443

444 **SMALP assays with divalent cations.** To determine the effect of SMALPs on
445 DNase activity, we prepared SMALPs from bacterial membranes as described
446 above. Three samples were made for the assay, the first containing 9 μ l SMALP
447 solution, 10 ng phage λ DNA (New England Biolabs), and 2 U DNase I. The second
448 sample replaced the SMALPs with deionized water, and the third sample replaces
449 both the SMALPs and DNase I with water. The samples were incubated at 37°C for
450 20 minutes and ran on a 1% (w/v) agarose gel for 30 minutes at 20 V/cm.

451 To test inhibition of *Taq* polymerase by SMALPs, PCR reactions were made
452 containing 1x *Taq* polymerase Master Mix (NEB), 0.2 μ M forward
453 (TACGCCGGGATATGTCAAGC) and reverse primers
454 (TACGCCAGTTGTACGGACAC) that target the phage λ E gene, 0.1 ng phage λ
455 DNA. In one sample, 10x diluted SMALP solution was added. PCR program
456 consisted of 30 seconds at 95°C, 25 cycles of 30 seconds at 95°C, 30 seconds at
457 55°C, and 60 seconds at 72°C, and 5 minutes at 72°C. Samples were then run on
458 agarose gel as described above.

459 The effect of the divalent cations Ca^{2+} and Mg^{2+} was tested as follows. SMA
460 stocks of 6 mg/ml were incubated for 20 minutes in the presence of 0-40 mM of
461 either CaCl_2 (Sigma) or MgCl_2 . SMA precipitate was pelleted by centrifuging for 1
462 minute at 21,000 x *g*. Next, adsorption of the supernatant was determined at 259 nm
463 on a NanoPhotometer C40 (Implen). Concentrations were calculated using an SMA
464 standard curve with concentrations ranging from 0-40 mg/ml.

465

466 **ACKNOWLEDGEMENTS**

467 We thank Marie-Eve Aubin-Tam (TU Delft), Arjen Jakobi (TU Delft), Martijn C.
468 Koorengel (Utrecht University), and J. Antoinette Killian (Utrecht University) for
469 their helpful advice.

649
650
651 **Figure 1: Styrene maleic acid lipid particles (SMALPs) can be made from**
652 **distinct microbial membranes.** (a): A schematic of the process by which styrene
653 maleic acid co-polymer incorporates itself into lipid membrane to isolate membrane
654 proteins in SMALPS. (b): SMALPs can be made from Gram-positive and Gram-
655 negative bacterial membranes at roughly equal efficiency. Optical densities of *E. coli*
656 K12 and *B. subtilis* 110NA membrane suspensions (10 mg/ml) rapidly decreased
657 upon addition of 20 mg/ml SMA (at grey vertical line) due to dissolution of large
658 membrane particles into SMALPs. (c): SMALPs of *B. subtilis* are larger than SMALPs
659 of *E. coli*, as shown by diameter distributions of SMALPs from the two species
660 obtained through dynamic light scattering. Each sample was measured in triplicate,
661 with the replicates plotted on top of each other. Solid lines are the average of the
662 three replicates.

663

664 **Figure 2: SMALPs decrease viable phage counts.** (a): Inhibition of lytic activity by
665 *Bacillus* phage $\phi 29$ (10^6 pfu/ml, starting MOI: 10^{-2}) and *Escherichia* phages λ (10^5
666 pfu/ml, starting MOI: 10^{-3}) and T4 (10^4 pfu/ml, starting MOI: 10^{-4}) by SMALPs
667 prepared from their hosts. Liquid cultures of host cells were either not infected
668 (SMALPs-only control, light grey), infected with SMALPs-incubated phage (red), or
669 infected with untreated phage (phage-only control, dark grey), followed by
670 measurement of optical densities at 600 nm every 10 minutes. Points are
671 measurements in each biological triplicate, solid lines are the mean. (b): Time-
672 dependent decrease of viable phage counts by SMALPs. Samples were taken at 5-
673 minute time intervals of phages incubated with SMALPs from their host and used for
674 plaque assays. The percentage of viable phages were estimated using a non-treated
675 phage control. Points are replicates, while solid lines are means.

676

677 **Figure 3: Specificity of ejection by various phages upon addition to SMALPs.**

678 (a): Ejection of phage λ DNA in the presence of *E. coli* K12 SMALPs. YO-PRO
679 fluorophore was added to phage λ stock (light grey), *E. coli* K-12 SMALPs (dark grey)
680 and a combination of the two and fluorescence was measured after a 20-minute
681 incubation. Points are biological replicates. (b) and (c): YO-PRO fluorescence assays
682 like (a) performed with phages λ and $\phi 29$ added to *E. coli* K12 and *B. subtilis*
683 SMALPs. SMALP-only measurements were subtracted from the SMALP + phage
684 measurements, phage measurements were negligible (see (a)). (d): Receptor
685 specific DNA ejection by phage λ after incubation with SMALPs from *E. coli* K12 or
686 Δ LamB, as measured by QuBit DNA quantification assays. The experiments were
687 repeated thrice, each instance (which have different shades of red) composed of
688 biological triplicates (individual points). SMALP-only measurements were subtracted
689 from SMALP + phage incubations. Significance values are according to Welch two-
690 tailed t-tests, * <0.05 , ** <0.01 , *** <0.001 , **** <0.0001 .

691

692 **Figure 4: Chelating activity of SMALPs causes inhibition of DNA-modifying**

693 **reactions.** (a): DNase inhibition by SMALPs, shown by an agarose gel of λ DNA with
694 SMALPs and DNase, λ DNA with DNase, and λ DNA alone. (b): Inhibition of *Taq*

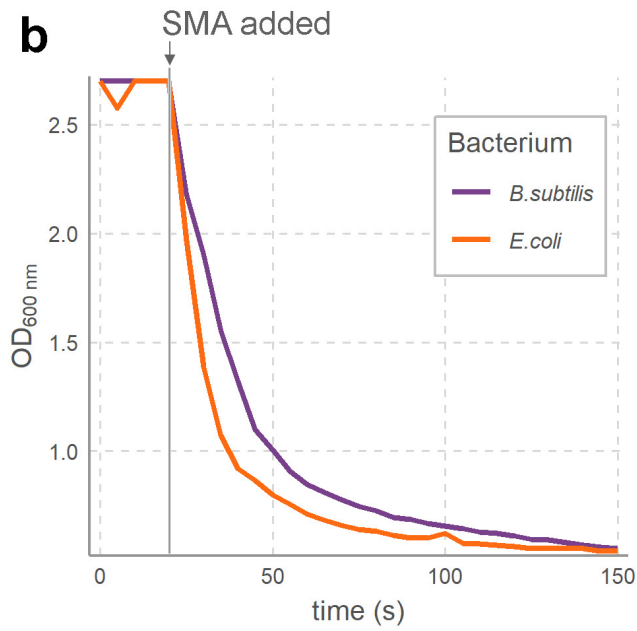

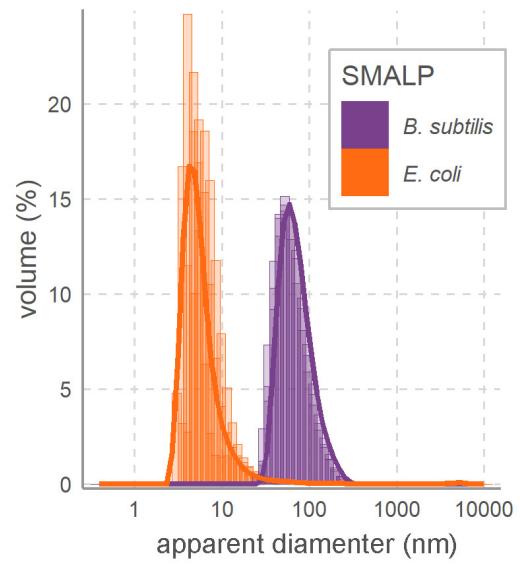

695 polymerase by SMALPs after PCR targeting λ DNA. (c) Precipitation of SMA by
696 addition of divalent cations in calcium chloride (Ca) and magnesium sulphate (Mg),
697 followed by centrifugation. SMA concentration was determined by adsorption at 259
698 nm and comparison to a standard curve (Figure S2). Points are replicates, solid lines
699 are averages.

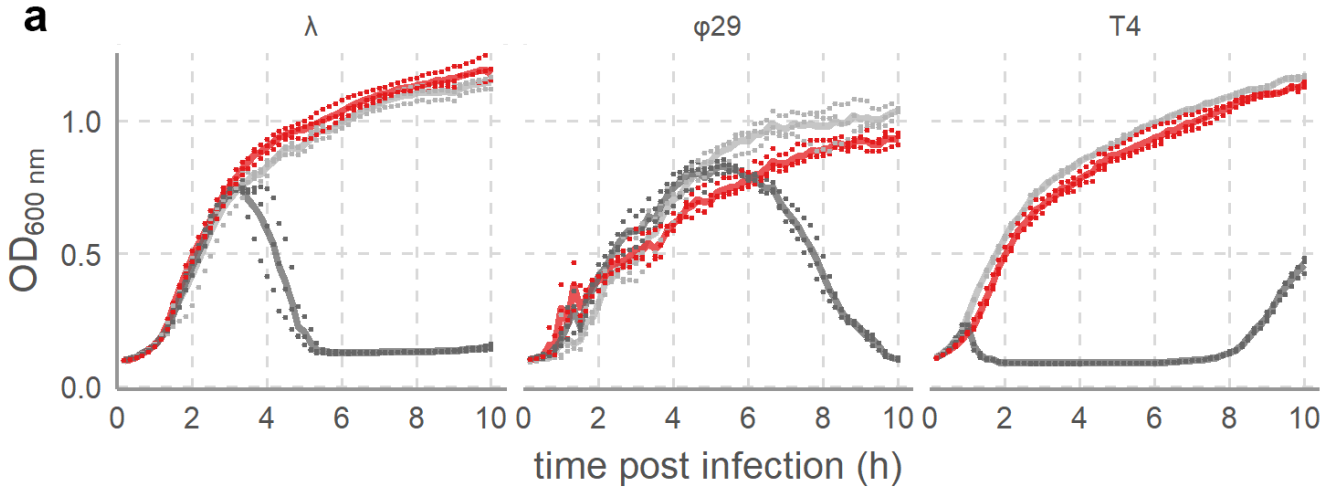

700

701 **Table 1: Characteristics of model phages used to test the inhibitory effect of**
702 **SMALPs.**

Phage	Family	Host used	Classification	Receptor(s)
λ	<i>Siphoviridae</i>	<i>E. coli</i> BW25113	Gram-negative	LamB protein (66)
T4	<i>Myoviridae</i>	<i>E. coli</i> BW25113	Gram-negative	OmpC protein/LPS (67)
ϕ 29	<i>Podoviridae</i>	<i>B. subtilis</i> 110NA	Gram-positive	Teichoic acids (37)
