The acid-catalysed formation of glycosidic bonds is more difficult when glycosyl donors are fluorinated, especially at the 2-position. Here we report high-yielding glycosidation and glycosylation reactions of 2,3-difluorinated- and 2,3,4-trifluorinated gluco- and galactopyranoside donors with a variety of acceptors under conventional trichloroacetimidate/TMSOTf activation in moderate to high anomeric selectivities. This methodology allows access to highly fluorinated glycans, illustrated with the synthesis of a pentafluorinated disaccharide.

Glycans are a large class of biomolecules that have important roles in diverse areas such as human health and biomaterials.^{1,2} The study of how glycans interact with proteins and how glycan structure determines materials properties is therefore of great importance. Selective fluorination of glycans is one of the strategies that enable such studies. It can be used for epitope-mapping studies, for example by comparing binding affinities^{3,4} or by using ¹⁹F NMR based experiments,⁵ for ¹⁸F based diagnostic applications,⁶ or fluorine can be introduced to deliberately modify protein-carbohydrate interactions as its small size, high electronegativity, and non-polarizable electron pairs affect most of the interaction mechanisms.⁷ Finally, carbohydrate fluorination influences their hydrolytic and enzymatic stability, and has received attention for property optimisation in a drug development context.^{8,9} Insights in glycan-based materials properties can be obtained by fluorination, which disrupts local hydrogen bonding networks.^{10,11}

In the vast majority of cases, monofluorinated sugar units are employed. Site-selective fluorination, even of smaller oligosaccharides, is not trivial, and glycosylation involving fluorinated monosaccharide building blocks is usually the only practical way to obtain fluorinated glycans. Enzymatic

glycosylations are possible,^{12,13} but so far only work with monofluorinated donors.¹⁴ Fluorination has a negative effect on glycosylation rates because its strong electron withdrawing effect destabilizes glycosylation transition states.⁷ Chemical synthesis of glycans involving one or more monofluorinated sugar building blocks has been successfully demonstrated.^{15,16}

Glycosylation involving polyfluorinated donors is less common,¹⁷ and demonstrated with 2,6-^{18,19} and 3,6-²⁰ difluorinated donors (Fig. 1A). With fluorination at successive carbon atoms next to the anomeric centre, only glycosidation reactions have been reported (Fig. 1B). With a hexafluorinated donor, DiMagno notably achieved glycosidation using the very reactive triflate leaving group.²¹ Our group reported an anomeric

alkylation approach for the related tetrafluorinated donors.^{22,23} Both strategies were successfully employed by the Giguère group for the first glycosidations of 2,3,4-trifluorinated donors, using an *in situ* generated glycosyl bromide with phenolate nucleophiles,^{24,25} or using Ag₂O induced anomeric alkylation with alkyl iodides.²⁶ Unfortunately, this method was shown not to work for glycosylation with a 6-iodinated galactose acceptor. Using the same donor, BF₃·OEt₂-mediated S_N1-type anomeric alkylation also led to good results (not shown).^{26,27}

Incorporation of polyfluorinated sugars into glycans will enable novel opportunities for the study of protein-carbohydrate interactions and glycan-based biomaterials. As anomeric alkylation is inherently less attractive for this purpose, not least due to the inevitable inversion of configuration at an acceptor ring position, a conventional glycosylation approach is desired. Here we report our first results of glycosidation and glycosylation of 2,3-difluoro- and 2,3,4-trifluorinated glucose and galactose donors (Fig. 1C).

Anticipating a low donor reactivity, our attention went first to the use of glycosyl triflates as donors, which were synthesised by treatment of the reducing sugar with Tf₂O. However, they proved too reactive to be isolated, and their reaction with excess methanol as acceptor led to a complex reaction mixture. The corresponding tosylate donor, which was synthesised by reaction of the hemiacetal with Ts₂O, was stable enough to be isolated, but glycosidation reactions also led to complex reaction mixtures. To our delight, attempts to use the conventional trichloroacetimidate group as donor proved successful, prompting their further investigation.

The syntheses of the trichloroacetimidate donors was achieved according to the procedure developed by Schmidt *et al.*²⁸ using the corresponding reducing sugar, 10 equiv. of trichloroacetonitrile, and 0.1 equiv. of DBU (Scheme 1). The reaction was stirred overnight to maximise the formation of the α -anomer, and high yields and selectivities were obtained. Deactivating ester protecting groups were selected in the first instance as a ‘worst case’ reactivity scenario.

To enable comparison with Gilmour’s seminal work on 2-F glucose and -galactose donors,²⁹ glycosidation with 2-propanol under TMSOTf catalysis was investigated first. In our hands, increasing the equivalents of TMSOTf from 0.1 to 0.2 and using rigorously dry conditions including distilled dichloromethane

Scheme 1 Syntheses of the trichloroacetimidate donors.

Table 1 Influence of the temperature

Temp.	Yield ^a (α/β ratio ^b)	
	13 (Glc)	14 (Gal)
−60 °C	c	32% (1/17)
−50 °C	c	97% (1/8.6)
−40 °C	52% ^d (1/5.6)	98% (1/5.4)
−30 °C	> 99% (1/3.2)	90% (1/4.0)
−20 °C	93% (1/2.5)	> 99% (1/2.2)
0 °C	> 99% (1/1.3)	c
Rt	> 99% (1.2/1)	> 99% (1/1.1)
40 °C	> 99% (1.2/1)	c

solvent over CaH₂ was required to achieve reproducible reactions. In order to ensure quantitative integration of anomeric ratios by ¹⁹F{¹H} NMR analysis of the crude reaction mixture, a delay time of 3 s was used. The glucose and galactose donors **7** and **11** were investigated first (Table 1). In general, reactions proceeded in excellent yields with the glucose donor displaying a lower reactivity compared to the galactose donor, for which almost quantitative yields were obtained even at −50 °C. This was a surprising finding, given the corresponding peracetylated 2-deoxy-2-fluoro galactose trichloroacetimidate was reported not to react below 0° (leading to 45% yield of the isopropyl glycoside).^{‡16,30} The anomeric selectivity is enhanced in favour of the β -anomer at lower temperature, with high β -selectivities obtained for the galactose donor. Reaction of the glucose donor **7** at room temperature or higher resulted in the α -glycoside as the major anomer in a 1.2/1 ratio.

The glycosidation was then investigated with the different donor substrates (Table 2), all at temperatures of −30 °C. For the glucose donors, the change of an acetate for a benzyl group (**8**) led to a slight decrease in yield and anomer ratio, which was unexpected based on Gilmour’s report of pronounced

Table 2 Glycosidation of different donors at −30 °C

Donor X (Y = H)	Glucoside Yield ^a (α/β^b)		Galactoside Yield ^a (α/β^b)	
	Donor X (Y = H)	Donor Y (X = H)	Donor X (Y = H)	Donor Y (X = H)
7 OAc	13 > 99% (1/3.2)	10 OAc	17 > 99% (1/4.7)	
8 OBn	15 86% (1/1.4)	11 OBz	14 90% (1/4.0)	
9 F	16 34% (1/2.1)	12 F	18 > 99% (1/9.0)

β -selectivity when using benzyl protecting groups.²⁹ With 2,3,4-trifluorination (**9**), a low 34% yield of **16** was obtained, in moderate ratio. For the galactose donors, the presence of a smaller acetate (**10**) instead of benzoate (**11**) slightly increased the anomeric product ratio, while reaction of the 2,3,4-trifluorinated galactose donor **12** yielded the glycoside **18** in quantitative yield with a much higher 1:9 β -selectivity.

Next, glycosylation using sugar-based acceptors was investigated. Such glycosylations are more challenging, given the reduced reactivities of sugar alcohol groups. The six donors **7–12** were reacted with galactoside diacetone (Table 3). To enable comparison with the data in Table 2, reactions were also carried out at $-30\text{ }^\circ\text{C}$. For both the glucose and galactose donors, excellent yields were obtained, which were superior (in the case of glucose-based donors **7–9**) or similar (galactose-based **10–12**) compared to the isopropanol glycosidation yields. In contrast, in all cases significant erosion of the anomeric selectivities was observed compared to the results in Table 2.

The glycosylation scope of **11** and **12** was further investigated (Fig. 2). Glycosylation at the 4-position of a rhamnoside acceptor led to disaccharides **25** and **26** in excellent yield. In contrast, glycosylation at the 6-position of a 2-deoxy-2-azidogluco- and galactoside acceptor was low-yielding (**27**, **28**), although raising the temperature to $0\text{ }^\circ\text{C}$ was sufficient to obtain **28** in 89% yield. Glycosylation with a difluorinated acceptor at $-30\text{ }^\circ\text{C}$ to give the tetra- and pentafluorinated disaccharides **29** and **30** proceeded only in good yield with donor **10**, but increasing the temperature to $0\text{ }^\circ\text{C}$ significantly enhanced the yield. The anomeric selectivities were much reduced, with glycosylations to give **27** and **29** even displaying α -selectivity.

A control experiment was conducted to investigate the possibility of anomerisation under the reaction conditions (Scheme 2). A mixture of trichloroacetimidate **7** (1.0 equiv.) and isopropyl galactopyranoside **17** (1.0 equiv., α/β 1:5.2) were subjected to glycosylation conditions, with 1-propanol (2.4 equiv.) as acceptor at $0\text{ }^\circ\text{C}$. $^{19}\text{F}\{^1\text{H}\}$ NMR analysis of the crude reaction mixture indicated no change in the anomeric ratio of **17**, or any evidence for the formation of cross-glycosylation products such as **13** or **32**. Hence, the reaction is not reversible under the employed reaction conditions

Fig. 2 Glycosylation results with other acceptors.

Scheme 2 Control experiment regarding in-situ anomerisation.

(Scheme 2). Incidentally, the higher anomeric ratio of the glycosidation product **31** compared to that of the isopropyl glycoside (1:1.3 α/β , Table 1) is expected given the lower steric hindrance of propanol.³⁰

A tentative model for the observed anomeric selectivities of the peracetylated donors, limited to the $^4\text{H}_3$ and $^3\text{H}_4$ halfchair conformations, is shown in Fig. 3. The reactivity of the acetylated polyfluorinated donors is clearly similar compared to the peracetylated 2-deoxy-2-fluoroglc/gal trichloroacetimidates investigated by Gilmour,^{29,30} While this was not expected, fluorine and acetate groups do have similar ‘field inductive effect parameters’.³¹ Hence, a similar “ $\text{S}_{\text{N}}1$ -like”²⁹ transition state (TS) is assumed as well as the preponderance of the

Fig. 3 Simplified model to describe the anomeric selectivities. (a) **32** = isopropyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluorogluco- and galactoside, See ref. 29. (b) **33** = isopropyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluorogalactoside, See ref. 30.

Anh-Eisenstein 1,2-induction model placing F2 in axial position.²⁹ This leads to the ³H₄ halfchair as lower-energy transition state, in accordance with the generally observed β-selectivity. When glucose-configured, substituents at the 3- and 4-position are axial, which has been reported to individually lead to stabilisation of the TS,³² but as part of a glucose framework also undergo destabilising steric interactions,^{32,33} leading to lower levels of β-selectivities. This could be the reason why **13**, with a small fluorine at C3, is formed with higher selectivity compared to **32**, which has a larger acetate group at C3. There may also be unfavourable 1,3-diaxial interactions between the substituents at the 2- and 4-positions, which will be larger with a 4F substituent, consistent with a lower β-selectivity for **16**. For the galactoses, the substituent at the 4-position is equatorial, which is also expected to destabilise the positive charge at the reacting centre. This effect may lead to a shift in reaction mechanism away from S_N1, which would favour β-selectivity. Glycosylation with the less reactive sugar acceptors is expected to give increased S_N1 character.³⁴ Larger nucleophiles also experience repulsion from the axial substituent at C3,³⁵ which reduces β-selectivities, as observed (Table 3 and Fig. 2). These data show that this reduction in β-selectivity is much more pronounced with a 4-OBz substituent compared to 4F, indicating that the effect of a 4-OBz group further increases the TS energy difference in favour of the ⁴H₃ halfchair, for which it is tempting to invoke remote ester participation.³⁶ However, there are other effects at play, including involvement of covalent glycosyl triflates and hyperconjugative stabilisations, as well as the presence of other oxonium ion conformations.^{33,37,38}

In summary, a series of novel 2,3-difluorinated and 2,3,4-trifluorinated glucose and galactose trichloroacetimidates are excellent donors for both glycosidation and glycosylation under typical Lewis-acid catalysed conditions, despite their high fluorination content. Excellent anomeric selectivities were obtained for glycosidation reactions with isopropanol, but glycosylation reactions using less reactive alcohol acceptors generally proceeded with low selectivities. As expected, galactose configured donors are more reactive. The glycosylation allows the synthesis of polyfluorinated disaccharides with multiple fluorination in each ring. Further optimisations to increase anomeric selectivities are ongoing. This convenient glycosylation of polyfluorinated glycosyl donors opens up new avenues in glycan-based glycobiology and materials research.
