## ABSTRACT

Bubble dynamics near a rigid boundary at Reynolds numbers of  $O(10-100)$  exhibit significant viscous effect, associated with ultrasonic cavitation and cavitation damage. We study this phenomenon experimentally using high-speed photography of spark-generated bubble oscillation in silicone oils, whose viscosity is about three orders larger than water. Comparing to bubbles in water, bubble surfaces in silicone oil are more stable and thus more cycles of oscillations may be observed and studied. Additionally, we investigate this phenomenon numerically using the volume of fluid method. We propose a non-reflective boundary condition, reducing the computational domain's dimensions tenfold based on the far-field asymptotic behavior. This paper pays particular attention in the mechanism for the bubble jetting, the vortex sheet, and the vortex ring development. Initially, a stagnation point at the bubble center moves away from the wall owing to asymmetric bubble expansion, leaving the bubble around the moment the bubble reaches its maximum volume. During this process, a vortex sheet forms inside the bubble. As the vortex sheet approaches the bubble interface, it transfers momentum to the gas-liquid interface, influencing the flow near the bubble wall. The high-pressure zone at the stagnation point drives the distal bubble surface to collapse first and fastest subsequently. This asymmetric collapse generates circulation around the bubble's side cross section, leading to the development of a vortex ring within the bubble gas at the outer rim of the decaying vortex sheet. The vortex ring, with its core inside the bubble gas, functions like a bearing system in accelerating the jet.

## I. INTRODUCTION

In this work, we study viscous bubble dynamics for a Reynolds number of  $O(10-100)$  as it relates to the start of a cavitation collapse, in order to identify the cause of the indentation in the bubble wall from which the later, high-speed and inertia-controlled jetting process grows. Viscous effects are essential for cavitation bubbles, whose population comprises mainly very small bubbles. The experimental studies for the bubble distributions of various cavitation structures (bubble filaments, bubble clusters, and the acoustically cavitating jets) have shown a centroid at approximately an equilibrium radius of  $2-4 \mu\text{m}$ .<sup>1</sup> Hydrodynamic cavitation is associated with wide and important applications, including damage to pumps, turbines, and propellers.<sup>2-5</sup> Acoustic cavitation also has applications in biomedical ultrasound,<sup>6-11</sup> sonochemistry<sup>12</sup> and cavitation cleaning.<sup>13-16</sup>

Experimental studies of collapsing bubbles capable of eroding metal have been largely focused on bubbles with radii  $O(100) \mu\text{m}$  or larger with  $Re = O(10^3)$  or larger.<sup>17-33</sup> Although other options are available,<sup>34,35</sup> bubble dynamics are widely modeled using the boundary integral method based on potential flow theory.<sup>36-47</sup> Viscous bubble dynamics have also been simulated successfully based on the Navier-Stokes equations coupled with various interface-capturing schemes.<sup>48-59</sup> These computations are for  $Re = O(10^3)$  or larger.

It is well known that the chemical consequences of cavitation are essentially determined by the conditions inside a collapsing bubble.<sup>60,61</sup> This collapse will not only occur at rigid boundaries but also when two bubbles are in close proximity in the cloud.<sup>62</sup> Our research will accurately simulate the fluid mechanics of the bubble gas during the asymmetric collapse.

We perform both experiments and computations for bubble dynamics. Experimental studies provide direct observation of bubble oscillation. Computations provide the detail on the generation and the evolution of the vortex sheet, the vortex ring, the flow field, the shockwave propagation, the jet development and impact on the rigid boundary, and the shear stress at the rigid boundary.

We conduct experiments for electric spark-generated bubbles in silicone oils with a high-speed camera. The use of spark-generated bubbles in water to study non-spherical bubble collapse, and the formation of jets is a well-established technique, in almost continuous use in research of this phenomenon from the 1980s<sup>63</sup> to recent years.<sup>64–67</sup> Ohl *et al.*<sup>68</sup> provide an excellent review. The hardware deployed in this research is substantially similar to that used in many water-based studies, but with the difference that the sparks are generated in silicone oil, not water.<sup>69</sup> This is because the viscosity of silicone oils are two to three orders larger than that of water. To perform experiments at the same Reynolds number for the processes that occur at the start of the collapse when the indentation forms, bubble size in silicone oils are two to three orders larger than that in water. More specifically, to carry out experiments for bubbles with  $Re = O(10-100)$  in water, bubbles radii are  $O(1-10) \mu\text{m}$ . The dynamics of microbubbles poses technical challenges owing to the high spatial and temporal resolution requirements. To carry out experiments for bubbles with  $Re = O(10-100)$  in silicone oils, bubbles radii are  $O(1-10)$  mm. Another advantage of using a high-viscosity liquid is that bubble surfaces in water often become unstable after the first cycle of oscillation. Bubble surfaces in silicone oil are more stable, and thus, more cycles of oscillations may be observed and studied.

Our numerical simulations are based on the compressible Navier–Stokes equations using OpenFOAM,<sup>70</sup> following Koch *et al.*,<sup>51</sup> Lechner *et al.*,<sup>53,54</sup> and Zeng *et al.*<sup>57</sup> One of the challenges in the computations is associated with the requirement for a large computational domain. To prevent the reflection from the far field, its typical dimension is on the order of  $O(100R_{max})$ , where  $R_{max}$  represents the maximum bubble radius. Another challenge is that the mesh and temporal resolution must be fine enough across the entire computational domain to model shockwave propagation accurately. The loss of energy associated with the emission of shockwaves at the end of the collapse was not accurately captured in the previous computations. This could be due to the mesh size not being fine enough for simulating the radiation of shockwaves. In order to circumvent this issue, a portion of the bubble's potential energy was manually removed at the end of the first cycle of oscillation to continue the computations and to achieve agreement with experiments for the second cycle.<sup>57</sup> Therefore, any development in the numerical model that can reduce the computational cost is highly desirable.

To resolve the aforementioned two problems, a non-reflective boundary condition is proposed based on the far-field asymptotic behavior, which is obtained from the weakly compressible theory.<sup>37,39,40</sup> This reduces the dimension of the computational domain tenfold. With this reduction in domain size, a sufficiently fine grid can be used for the computational domain to capture the shockwaves' radiation accurately. Our simulated bubble dynamics agree very well with experiments for both the first and second cycles of oscillation without manually adjusting the potential energy at the end of the first collapse.

We further study viscous bubble dynamics near a flat rigid boundary with  $Re = O(10-100)$  and compare the results with that for

$Re = O(10^3)$ , in terms of bubble evolution, jet development, shockwave propagation, and the shear stress on the rigid boundary. In particular, we reveal that the vortex ring associated with a toroidal bubble is not generated instantaneously as the liquid jet penetrates the bubble but converts from a vortex sheet within the bubble gas during the later stages of expansion and subsequently develops.

The remainder of the paper is organized as follows: Sec. II details the experimental setup and numerical model. In Sec. III, experimental results are presented for oscillations of both spherical and non-spherical bubbles. Numerical studies are further performed for bubble dynamics near a rigid boundary in Sec. IV, which correlates well with the experimental data, and viscous effects on bubble dynamics are discussed. Finally, the conclusions of the study are given in Sec. V.

## II. METHODOLOGY

In this section, we describe both the experiment setup and the computational model. The experiment uses a high-speed camera for electric spark-generated bubbles in silicone oils. The computational model is based on the volume of fluid method for two-phase viscous compressible flows.

### A. Experiment

The experiment is carried out for electric spark-generated bubbles in silicone oils. Figure 1(a) illustrates the experimental setup used to generate a cavitation bubble and record its dynamics. The experiment is performed in a cubic acrylic container ( $0.3 \times 0.3 \times 0.6 \text{ m}^3$ ) filled with the liquid (water or silicone oils) to a depth of 0.2 m. The container is illuminated by a 2 kW LED non-strobe lamp positioned on the opposite side of the camera, passing through a white frosted glass film and a soft light plate. This arrangement allows for a more uniform projection of the light source. The images of the cavitation bubble are captured by a VRI-Phantom V611 high-speed camera working at 7900 frames per second (FPS) for  $1280 \times 800$  resolution.

As shown in Fig. 1(b), the bubble is generated by an electric spark device. It comprises a 205 V DC power supply, a 1 k $\Omega$  resistor, a 6600  $\mu\text{F}$  capacitor, and overlapping electrodes made of copper alloy. As mentioned in Cui *et al.*,<sup>32</sup> electrodes extending from the capacitor poles are crossed and touched at their other ends in the liquid. Upon activating switch K1, the power supply converts 220 V AC into 205 V DC and the capacitor is charged to 205 V. This discharges the electronic energy instantaneously, leading to heating at the cross point, bubble generation, and simultaneous activation of the information acquisition button on the high-speed camera. The copper alloy wires, with a thin radius of 0.1 mm compared to the bubble radius of approximately 15 mm, are anticipated to have a minimal impact on the bubble dynamics.

Figure 2 shows the configuration of a bubble in the container in the experiment. The dimensionless standoff distance  $\gamma$  is defined as  $D/R_{max}$ , where  $D$  is the distance from the center of the initial bubble to the bottom of the container and  $R_{max}$  is the maximum bubble radius attained in the experiment. As the bubble is about  $7R_{max}-10R_{max}$  from the side walls of the container and the free surface, their effects on bubble dynamics are assumed to be negligible as the amplitude for the spherically symmetric shockwaves emitted by the bubble depends on the reciprocal of the distance traveled.

We choose the length scale  $R_{max}$  and the pressure scale  $p_\infty - p_v$ , where  $p_\infty$  is the hydrostatic pressure of the liquid, and  $p_v$  is the partial

FIG. 1. (a) Experimental setup used to generate a cavitation bubble and record its dynamics, and (b) Underwater discharge circuit, which is comprised of a 205 V DC power supply, a 1 kΩ resistor, a 6600 μF capacitor, and overlapping electrodes made of copper alloy.

FIG. 2. Sketch of the bubble in a container filled with the liquid to a depth of 0.2 m in the experiment.  $D$  is the distance from the center of the initial bubble to the bottom of the container.

pressure of vapor inside the bubble. The Reynolds number and the Weber number of the bubble are defined as

$$Re = \frac{R_{max} \sqrt{\rho_{\infty}(p_{\infty} - p_v)}}{\mu_l}, \quad We = \frac{R_{max}(p_{\infty} - p_v)}{\sigma}, \quad (1)$$

where  $\rho_{\infty}$  is the undisturbed density,  $\mu_l$  is the dynamics viscosity, and  $\sigma$  is the surface tension coefficient of the liquid.

### B. Numerical simulation

In this subsection, the numerical model is described based on the compressible Navier–Stokes equations and the volume of fluid method.<sup>28,45,47,57–59,71–73</sup> A non-reflective boundary condition is proposed based on the asymptotic behavior, which reduces the dimension of the computational domain tenfold.

#### 1. Numerical model

*a. Equations of motion.* In the volume of fluid (VOF) method, the two-phase flow of liquid and gas is treated as a “single-phase” flow. The fluid density  $\rho$  and viscosity  $\mu$  are expressed in terms of the volume fraction parameter  $\alpha$  of the liquid,

$$\rho = \alpha\rho_l + (1 - \alpha)\rho_g, \quad \mu = \alpha\mu_l + (1 - \alpha)\mu_g, \quad (2)$$

where the subscripts  $g$  and  $l$  denote the gas phase and the liquid phase, respectively. Equation (2) takes account of the volume fractions for liquid and gas being  $\alpha$  and  $1 - \alpha$ , and is the statistically correct for the two-phase flow.

The single-phase flow is thus governed by the compressible Navier–Stokes equations,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0, \quad (3)$$

$$\frac{\partial(\rho \mathbf{u})}{\partial t} + \nabla \cdot (\rho \mathbf{u} \mathbf{u}) = -\nabla p + \nabla \cdot \tau + \mathbf{f}_{st}, \quad (4)$$

where  $t$  is the time,  $\mathbf{u}$  is the velocity field,  $p$  is the pressure,  $\tau = \mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T - \frac{2}{3}(\nabla \cdot \mathbf{u})\mathbf{I})$  is the stress tensor with the unit tensor  $\mathbf{I}$ , and  $\mathbf{f}_{st}$  represents the surface tension force acting at the interface of two fluids. It is treated as an external force for the single-phase flow acting at the interface, given as follows:<sup>74</sup>

$$\mathbf{f}_{st} = \sigma \kappa \nabla \alpha, \quad (5)$$

where  $\kappa = -\nabla \cdot \mathbf{n}$  is the curvature at the interface and  $\mathbf{n} = \nabla \alpha / |\nabla \alpha|$  is the unit normal to the interface.

Assuming no mass transfer between the two fluids, the mass conservation can be expressed as a continuity equation for each phase. For the liquid phase, it can be expressed as

$$\frac{\partial(\alpha \rho_l)}{\partial t} + \nabla \cdot (\alpha \rho_l \mathbf{u}) = 0. \quad (6)$$

This can be written as

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) = -\frac{\alpha}{\rho_l} \psi_l \frac{dp}{dt}, \quad (7)$$

where  $d/dt$  is the Lagrangian derivative;  $\psi_l = d\rho_l/dp$  is the compressibility of the liquid calculated from the equation of state.

Similarly, the mass conservation for the gas phase can be written as

$$\frac{\partial(1 - \alpha)}{\partial t} + \nabla \cdot ((1 - \alpha)\mathbf{u}) = -\frac{1 - \alpha}{\rho_g} \psi_g \frac{dp}{dt}, \quad (8)$$

where  $\psi_g = d\rho_g/dp$  is the compressibility of the gas. Combining Eqs. (7) and (8) yields

$$\nabla \cdot \mathbf{u} = - \left( \frac{\alpha}{\rho_l} \psi_l + \frac{1-\alpha}{\rho_g} \psi_g \right) \frac{dp}{dt}. \tag{9}$$

Combining Eqs. (7) and (9) gives us

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) = \alpha(1-\alpha) \left( \frac{\psi_g}{\rho_g} - \frac{\psi_l}{\rho_l} \right) \frac{dp}{dt} + \alpha \nabla \cdot \mathbf{u}. \tag{10}$$

To avoid numerical dissipation and retain the sharpness of the interface, an artificial “interface compression” term  $\nabla \cdot (\alpha(1-\alpha)\mathbf{u}_c)$  is added to the equation, where  $\mathbf{u}_c = |\mathbf{u}|\mathbf{n}$  is the compression velocity,

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) + \nabla \cdot (\alpha(1-\alpha)\mathbf{u}_c) = \alpha(1-\alpha) \left( \frac{\psi_g}{\rho_g} - \frac{\psi_l}{\rho_l} \right) \frac{dp}{dt} + \alpha \nabla \cdot \mathbf{u}, \tag{11}$$

which is the transport equation of the volume fraction  $\alpha$  determining the transient bubble surface.<sup>51,57–59,75</sup>

The Tait equation<sup>76</sup> is adopted for the liquid phase,

$$\rho_l = \rho_\infty \left( \frac{p+B}{p_\infty+B} \right)^{1/n_T}, \tag{12}$$

where  $n_T = 7.15$  and  $B = 3.046 \times 10^8$  Pa.

The oscillation of the bubble gas is assumed to be adiabatic,

$$\rho_g = \rho_{ref} \left( \frac{p}{p_{ref}} \right)^{1/\gamma_h}, \tag{13}$$

where  $\rho_{ref}$  and  $p_{ref}$  are the reference density and pressure of the bubble gas, and  $\gamma_h$  is the ratio of the specific heats of the gas, which is assumed to be constant over the time of the observation.<sup>77</sup>

To avoid the accumulation of numerical error for the mass of the bubble gas, the density of gas is updated using the conservation of mass, following Koch *et al.*,<sup>51</sup>

$$\rho_g(t) = \frac{\rho_g(0)V(0)}{V(t)}, \tag{14}$$

where  $\rho_g(t)$  and  $V(t)$  are the gas density and the volume of the bubble at time  $t$ , and  $\rho_g(0)$  and  $V(0)$  are their initial values. Here, the density of the bubble gas is assumed to be uniform in space.

*b. Non-reflective boundary condition at the far field.* A finite truncated domain is necessary for numerical modeling to represent the infinite liquid domain. To ensure the non-reflection of shockwaves at the external boundary, a large, truncated domain with the dimension being about  $100R_{max}$  is necessary,<sup>50,53,54</sup> leading to a considerable demand for computational resources. Here,  $R_{max}$  is a bubble’s maximum radius in an unbounded, incompressible, inviscid liquid. In the following, we formulate the far-field boundary condition using the asymptotic solution to reduce the size of the truncated domain and avoid the unphysical reflection of shockwaves at the external boundary.

Wang and Blake<sup>39,40</sup> developed the weakly compressible theory for non-spherical bubble dynamics based on the compressible potential flow theory, using the method of matched asymptotic expansions. They obtained the asymptotic analytic solution for the flow far away

from a bubble oscillating near a rigid flat boundary, in terms of the velocity potential  $\varphi(r, t)$ ,

$$\varphi(r, t) = -\frac{1}{2\pi r} \dot{V}(t - r/c), \tag{15}$$

where  $V(t)$  is the transient bubble volume at time  $t$ , the over dot denotes the derivative in time  $t$ ,  $r$  is the distance from a field point in the far field to the geometrical center of the bubble, and  $c$  is the speed of sound in the liquid. The liquid velocity  $\mathbf{u}(r, t)$  in the far field is given as follows:

$$\mathbf{u}(r, t) = u(r, t)\mathbf{e}_r = \left( \frac{1}{2\pi r^2} \dot{V}(t - r/c) + \frac{1}{2\pi cr} \ddot{V}(t - r/c) \right) \mathbf{e}_r, \tag{16}$$

where  $\mathbf{e}_r$  is the unit vector from the initial bubble centroid to the field point considered.

The far-field asymptotic solution (16) is obtained based on the potential flow theory but stands for the present viscous model, which is justified as follows. The viscous flow velocity  $\mathbf{u}(r, t)$  has the following Helmholtz’s decomposition:

$$\mathbf{u} = \nabla \varphi + \nabla \times \mathbf{A}. \tag{17}$$

The first component is irrotational and described by a scalar potential  $\varphi(r, t)$ . The second part is rotational, accounting for all the vorticity of the flow, and is described by a vector potential  $\mathbf{A}$ . To make this decomposition unique, it is assumed that  $\nabla \cdot \mathbf{A} = 0$ . The vector potential  $\mathbf{A}$  can be expressed in terms of the vorticity  $\omega(r, t)$  as follows:

$$\mathbf{A} = \frac{1}{4\pi} \int_{\Omega} \frac{\omega(\mathbf{r}', t)}{|\mathbf{r} - \mathbf{r}'|} dV'. \tag{18}$$

In this expression,  $\mathbf{r}$  is the field point, and  $\mathbf{r}'$  is the position of integration element  $dV'$  (the source point). The integral domain  $\Omega$  is the part of the liquid domain, where the vorticity is nonzero, with a length scale of  $R_{max}$ .

Klein and Ting<sup>78</sup> analyzed the far-field asymptotic behavior due to vorticity within a finite domain, with the following result:

$$\mathbf{A} = O(r^{-2}), \quad r \rightarrow \infty. \tag{19}$$

The velocity contribution stemming from the rotational component is of  $O(r^{-3})$  and decays faster than the velocity contribution of  $O(r^{-2})$  originating from the irrotational component. The far-field behavior of the velocity magnitude is thus given by Eq. (16) to the first two orders of approximation.

The pressure at the far field is obtained from the Bernoulli equation,

$$p = p_\infty - \frac{1}{2} \rho_l u^2 + p_d, \tag{20}$$

where  $p_d(r, t) = -\rho_l \frac{\partial \varphi}{\partial t} = \frac{\rho_l}{2\pi r} \ddot{V}(t - r/c)$ . We have

$$\begin{aligned} \int_0^t p_d(r, t) dt &= \frac{\rho_l}{2\pi r} \int_0^t \ddot{V}(t - r/c) dt = \frac{\rho_l}{2\pi r} (\dot{V}(t - r/c) - \dot{V}(0 - r/c)) \\ &= \frac{\rho_l}{2\pi r} \dot{V}(t - r/c). \end{aligned} \tag{21}$$

Here, we used  $\dot{V}(-r/c) = 0$  as the bubble oscillation has not started at time  $t = -r/c$ .

Substituting Eqs. (20) and (21) into Eq. (16) yields

$$c\rho_l u(r, t) = \frac{c}{r} \int_0^t p_d(r, t) dt + p_d(r, t). \quad (22)$$

This equation is similar to the early time approximations obtained for the fluid–structure interaction by Felippa.<sup>79</sup>

Initially, the bubble is spherical, and the flow field can be approximated using the method of images

$$\varphi(r, t) = -\frac{1}{4\pi r} \dot{V}(t - r/c) - \frac{1}{4\pi r_2} \dot{V}(t - r_2/c), \quad (23)$$

where  $r_2$  is the distance from a point considered to the image of the initial bubble centroid in the flat rigid boundary. The initial velocity field is obtained using  $\nabla\varphi$ , and the initial pressure field is obtained using the Bernoulli equation (20). The first- and second-order time derivatives of the bubble volume are obtained from the Keller–Miksis equation for spherical bubbles:<sup>80</sup>

$$\left(1 - \frac{1}{c}\dot{R}\right)R\ddot{R} + \frac{3}{2}\dot{R}^2\left(1 - \frac{1}{3c}\dot{R}\right) = \left(1 + \frac{1}{c}\dot{R}\right)\frac{p_l}{\rho_l} + \frac{R}{\rho_l c} \frac{dp_l}{dt}, \quad (24)$$

in which  $p_l$  is the pressure of the liquid at the bubble surface and given as follows:

$$p_l = p_{b0} \left(\frac{R_0}{R}\right)^{3\gamma_h} - \frac{2\sigma}{R} - (p_\infty - p_v) - \frac{4\mu_l}{R}\dot{R}, \quad (25)$$

where  $p_{b0}$  is the initial pressure of the bubble gas,  $R_0$  is the initial bubble radius,  $R$  is the transient bubble radius at time  $t$ ,  $\dot{R}$  and  $\ddot{R}$  are the first and second derivatives in time  $t$ , respectively.

### 2. Numerical setup

Consider an initially spherical bubble of high internal pressure inserted into the liquid at a standoff distance  $D$  from the boundary. As the computations are axisymmetric, a wedge-shaped domain with an

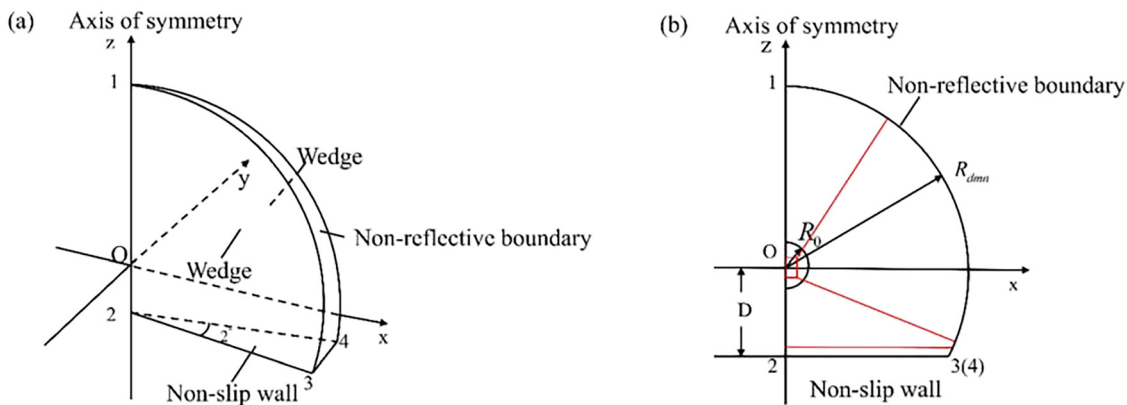

opening angle of 2 deg is constructed, with one cell wide in the azimuthal direction. The two planes shown in Fig. 3(a) are set as the wedge type in OpenFOAM to ensure axial symmetry. The essentially two-dimensional computational domain is bounded by the axis of symmetry, the flat rigid non-slip wall, and the non-reflective boundary at a distance of  $R_{dmn}$  to the origin in all directions.

The cross-sectional view of the mesh is shown in Fig. 3(b). The grid spacing is uniform in a rectangular domain within the initial bubble. Outside this rectangle, the domain is split into several blocks with the grid spacing growth rate being 1.01. The mesh near the rigid wall is refined to capture the flow within the viscous boundary layer. The adaptive time step is chosen to satisfy the CFL condition<sup>81</sup> with the maximum Courant number being 0.02 when capturing the shockwaves.

### 3. Numerical validation

*a. Validation of the non-reflective boundary condition at far field.* First, we validate the effectiveness of the non-reflective boundary condition at the far field. The case considered is a bubble with the maximum radius  $R_{max} = 600 \mu\text{m}$  at the dimensionless standoff distance  $\gamma = D/R_{max} = 1.1$ . The initial conditions are  $R_0 = 300 \mu\text{m}$ ,  $\dot{R}_0 = 20 \text{ m/s}$  and  $p_{b0} = 1500 \text{ Pa}$ , which are obtained by integrating the Keller–Miksis equations backward from its maximum radius and zero bubble wall velocity using the fourth-order Runge–Kutta method. Additional details can be found in Wang<sup>82</sup> for reference. The caption to Fig. 4 provides other parameters used for calculations. This case is calculated with the computational domains being  $R_{dmn} = 10R_{max}$  and  $100R_{max}$ , respectively. Figure 4 displays the excellent agreement for the equivalent bubble radius history  $R_{eq} = (3V/4\pi)^{1/3}$ , although one domain size is ten times larger than the other one. The CPU time is about 50 and 71 h for  $R_{dmn} = 10R_{max}$  and  $100R_{max}$  respectively, with the Courant number being 0.5. This confirms the accuracy and effectiveness of the non-reflective boundary condition at the far field. Consequently, the domain size is set to  $R_{dmn} = 10R_{max}$  for the remaining computations.

*b. Convergence tests.* The convergence tests are carried out for various element numbers, with the results displayed in Fig. 5(a) for the time histories of the equivalent bubble radius  $R_{eq}$  and Fig. 5(b) for the bubble

**FIG. 3.** Sketch of the geometry and the boundary conditions used for the simulations of bubble dynamics near a rigid boundary: (a) 3D view of the truncated computational domain and (b) 2D projection of the computational domain in the  $Oxz$ -plane. An initially spherical bubble of high internal pressure is inserted into the liquid at a distance  $D$  from the boundary.

**FIG. 4.** Comparison of the equivalent bubble radius histories  $R_{eq}$  obtained from different computational domain sizes  $10R_{max}$  and  $100R_{max}$ , respectively, for a bubble with the maximum radius  $R_{max} = 600 \mu\text{m}$  at the dimensionless standoff distance  $\gamma = 1.1$  from a rigid boundary. The initial conditions for the computation are  $R_0 = 300 \mu\text{m}$ ,  $\dot{R}_0 = 20 \text{ m/s}$  and  $p_{b0} = 1500 \text{ Pa}$ . Other parameters used for calculations are  $\rho_\infty = 998 \text{ kg/m}^3$ ,  $\rho_{ref} = 1.2 \text{ kg/m}^3$ ,  $p_\infty = p_{ref} = 101315 \text{ Pa}$ ,  $\mu_g = 1.73 \times 10^{-5} \text{ Pas}$ ,  $\mu_l = 0.001 \text{ Pas}$ ,  $\gamma_h = 1.4$ ,  $\sigma = 0 \text{ N/m}$ , and  $c = 1500 \text{ m/s}$ .

shapes at its maximum volume during the second cycle of oscillation. The figures display the convergence of the numerical model. The results for the two higher resolutions,  $N = 501\,671$  and  $756\,954$ , are almost identical for the equivalent bubble radius histories and the bubble shapes. Therefore,  $N = 501\,671$  is chosen for all the remaining calculations.

**III. EXPERIMENTAL RESULTS**

**A. Spherical bubble oscillation in the silicone oil**

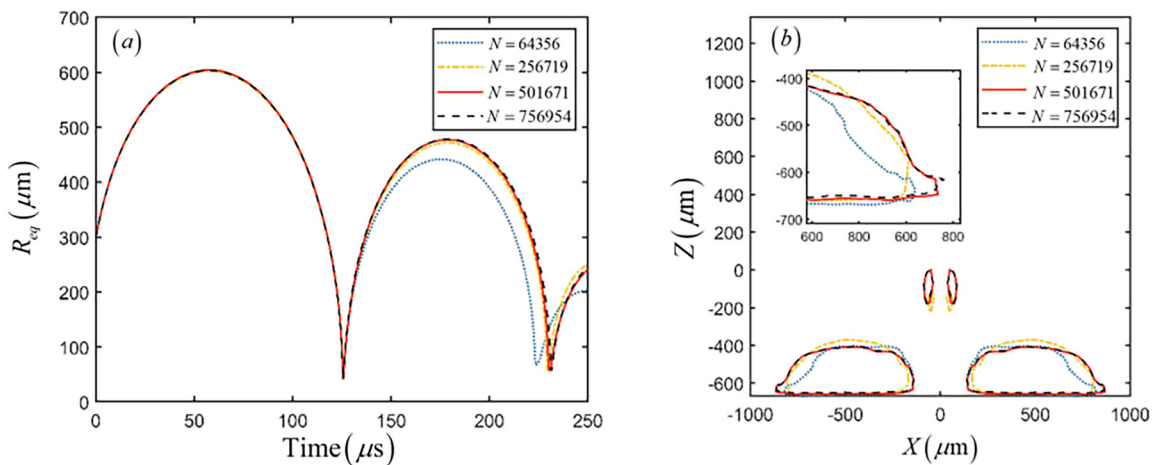

We first consider a bubble oscillating in an equivalent unbounded domain in the 1000cSt silicone oil with the density  $\rho_b$  the dynamic

viscosity  $\mu_b$ , and the surface tension coefficient  $\sigma$  being  $975 \text{ kg/m}^3$ ,  $0.975 \text{ Pa} \cdot \text{s}$ , and  $0.021 \text{ N/m}$ , respectively. Figure 6 shows the evolution of bubble shapes for two oscillation cycles. The bubble retains a nearly spherical shape during the oscillations. Figure 7 compares the equivalent bubble radius  $R_{eq}$  with the solution of the Keller–Miksis equation (24), where  $p_{b0} = 659 \text{ Pa}$ ,  $R_0 = 14.74 \text{ mm}$ ,  $p_\infty = 101\,315 \text{ Pa}$ , and  $\gamma_h = 1.4$ . Since the precise sound speed in silicone oils cannot be obtained using our experimental devices, we adapt the sound speed  $c$  in the Keller–Miksis equations to  $950 \text{ m/s}$  to align with the experimental data while ensuring it remains within a reasonable range.<sup>83</sup> As the temperature of the gas is high as a result of the thermal decomposition within the bubble induced by the copper wire, the vapor pressure  $p_v$  is set as  $31\,000 \text{ Pa}$  in the Keller–Miksis equation to fit with the oscillation period in the experiment. The saturation vapor pressure  $p_v = 31\,000 \text{ Pa}$  is also employed for determining the initial conditions and updating the far field boundary values in the simulations of bubbles within silicone oils. The theoretical curve in Fig. 7 for the initial expansion stage is obtained by integrating the Keller–Miksis equations backward from its maximum radius  $R_{max} = R_0 = 14.74 \text{ mm}$  and zero bubble wall velocity  $\dot{R}_0 = 0 \text{ m/s}$  with  $p_{b0} = 659 \text{ Pa}$ . There is good agreement between the experimental results and the Keller–Miksis equation. This agreement justifies the accuracy of the experimental measurements and the Newtonian fluid model with the parameters used in the calculation.

**B. Bubble oscillation near a rigid boundary in silicone oils**

The dynamics of bubbles near a rigid boundary are now under investigation within three distinct media: water, 500cSt silicone oil, and 1000cSt silicone oil. Properties of the three liquids are listed in Table I. The dynamic viscosities of 500cSt and 1000cSt silicone oils are  $0.485 \text{ Pa} \cdot \text{s}$  and  $0.975 \text{ Pa} \cdot \text{s}$ , being much larger than the water viscosity  $0.001 \text{ Pa} \cdot \text{s}$ .

Figure 8 displays the dynamics of a bubble near a rigid flat boundary located at the bottom of each frame for  $\gamma \approx 1.4$  in (a) water, (b) 500cSt silicone oil, and (c) 1000cSt silicone oil, respectively. As

**FIG. 5.** Convergence tests in terms of various element numbers: 64 356, 256 719, 501 671, and 756 954, for (a) the equivalent bubble radius  $R_{eq}$  histories and (b) the bubble shapes. Parameters used for calculations are the same as in Fig. 4.

**FIG. 6.** The evolution of bubble shapes for a spherical bubble oscillating in the 1000cSt silicone oil with the density  $\rho_l$ , the dynamic viscosity  $\mu_l$ , and the surface tension coefficient  $\sigma$  being 975 kg/m<sup>3</sup>, 0.975 Pa s, and 0.021 N/m, respectively.

**FIG. 7.** Comparison of the equivalent bubble radius  $R_{eq}$  history with the solution of the Keller–Miksis equation for a spherical bubble oscillating in the 1000cSt silicone oil for the case in Fig. 6. Other parameters used for the Keller–Miksis equation are  $p_{b0} = 659$  Pa,  $R_0 = 14.74$  mm,  $p_v = 31\,000$  Pa,  $p_\infty = 101\,315$  Pa,  $\gamma_h = 1.4$ , and  $c = 950$  m/s.

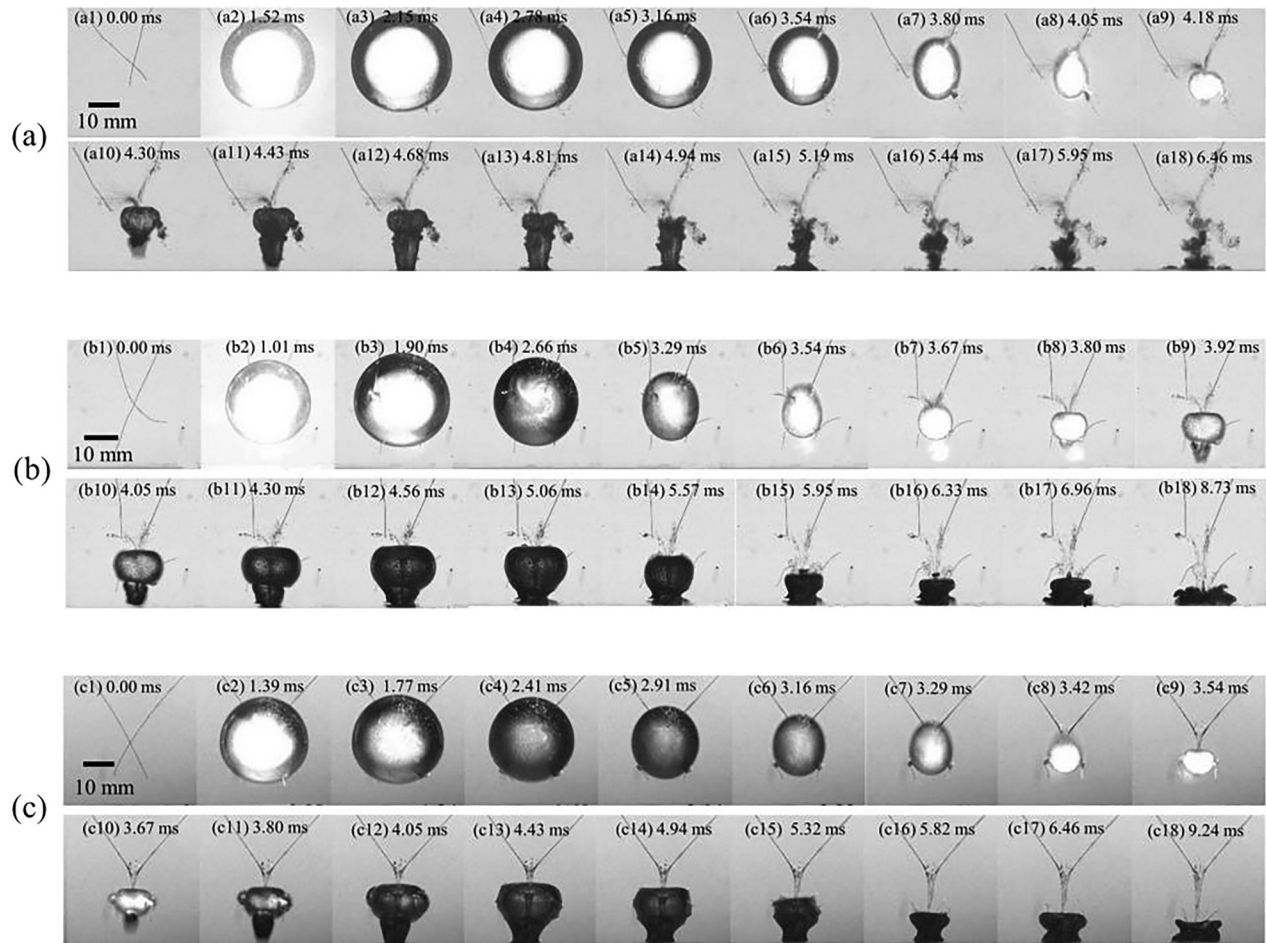

depicted in Fig. 8(a), the bubble in water initially undergoes spherical expansion in frames (a1)–(a3). Subsequently, it collapses into a vertically elongated prolate spheroid in frames (a3)–(a7). The bubble then collapses predominantly from the upper surface in frames (a7)–(a9). A jet forms and penetrates the bubble during the early stages of the rebound in frame (a9). As the bubble rebounds, the jet penetrates the liquid between the bubble and the wall, eventually impacting the wall in frames (a9)–(a12). It subsequently re-collapses and migrates to the wall in frames (a12)–(a18) when the instability develops at the bubble surface. The bubble disintegrates toward the end of the second cycle.

Figures 8(b) and 8(c) display similar features for the bubble dynamics in silicone oils. As in the case of water, the bubble expands spherically, first collapsing to a prolate spheroid, which is elongated vertically and then collapsing predominantly from the upper surface. Figure 9 shows the equivalent bubble radii  $R_{eq}$  history in the experiment. With much larger viscosities, the bubble maximum radii are smaller in silicone oils, 15.33 and 14.03 mm in 500cSt and 1000cSt silicone oils, compared to 16.35 mm in water. This is because of the more significant damping effects in silicone oils. Accordingly, the periods of the first cycle are smaller in silicone oils, being 3.80 and 3.54 ms in 500cSt and 1000cSt silicone oils, compared to 4.18 ms in water.

**TABLE I.** Properties of the liquids used in the experiment, the Reynolds and Weber numbers, the corresponding maximum equivalent bubble radius  $R_{max}$ , and the period for the first oscillation cycle  $P_1$ .

Type of liquid	$\rho_l$ (kg/m <sup>3</sup> )	$\mu_l$ (Pa · s)	$\sigma$ (N/m)	$Re$	$We$	$R_{max}$ (mm)	$P_1$ (ms)
Water	998	0.001	0.072	$1.63 \times 10^5$	$2.25 \times 10^4$	16.35	4.18
500cSt silicone oil	975	0.485	0.021	$3.08 \times 10^2$	$7.23 \times 10^4$	15.33	3.80
1000cSt silicone oil	975	0.975	0.021	$1.41 \times 10^2$	$6.62 \times 10^4$	14.03	3.54

**FIG. 8.** The evolution of bubble shapes for a bubble oscillating near a rigid boundary in (a) water with the viscosity  $\mu_l$  being 0.001 Pa s, (b) 500cSt silicone oil with the viscosity  $\mu_l$  being 0.485 Pa s, and (c) 1000cSt silicone oil with the viscosity  $\mu_l$  being 0.975 Pa s at the dimensionless standoff distance  $\gamma \approx 1.4$ . The densities  $\rho_l$  are 998, 975, and 975 kg/m<sup>3</sup>, respectively. The surface tension coefficients  $\sigma$  are 0.072, 0.021, and 0.021 N/m, respectively. The maximum bubble radii  $R_{max}$ , attained in the experiment are about 16.35, 15.33, and 14.03 mm, respectively.

As in the case of water, a jet forms during the early rebounding of the bubble, penetrating the bubble and then impacting the wall. However, both the maximum bubble radius and the oscillation period in the second cycle are significantly smaller for the bubble in water as in Fig. 9. This phenomenon is attributed to the additional energy dissipation stemming from surface instability and the formation of bubble clouds following jet impact and penetration through the bubble in water.<sup>84–86</sup> The bubble then re-collapses and migrates to the wall due to the Bjerknes force of the rigid boundary. In contrast to the scenario in water, the bubble maintains stability during the second cycle in the case of silicone oils. As a result, the jet is visible in frames (b11)–(b12) of Fig. 8(b) and frames (c12)–(c14) of Fig. 8(c). A protrusion of bubble gas encloses and follows the jet after the jet has penetrated the bubble.

#### IV. COMPUTATIONAL RESULTS

Computational results are presented and discussed in this section. This includes the validation of the computational model with experiments. Attention is paid to the generation and evolution of vortex

sheets, vortex rings, flow fields, shockwave propagation, jet development and impact on the rigid boundary, and the shear stress at the rigid boundary. These details are either unavailable or difficult to obtain from experiments.

#### A. Comparisons with experiments

We first compare the numerical results with our experimental results for the bubble oscillating in the 500cSt silicone oil with the viscosity being 0.485 Pa · s and Reynolds number being  $3.08 \times 10^2$  at the dimensionless standoff distance  $\gamma \approx 2.0$ . The computational domain size is  $10R_{max}$  and initial conditions used for calculation are  $R_0 = 10$  mm,  $\dot{R}_0 = 12$  m/s and  $p_{b0} = 720$  Pa. Other parameters used for calculations are provided in the caption to Fig. 10. The computational results are re-timed for the comparisons.

Figure 10 displays the bubble shapes at representative times. The computational and experimental results are shown on the left and right parts of frames (a1)–(f1), respectively. The rigid boundary is at the

FIG. 9. The equivalent bubble radii  $R_{eq}$  history in the experiment for cases in Fig. 8.

bottom of frames (a1)–(f1). Frames (a2)–(f2) represent the 2D views of the simulated bubbles, while frames (a3)–(f3) present their 3D perspectives. Figure 10(a) is for the bubble at its maximum radius when it remains spherical. It then begins to collapse and becomes a prolate

spheroid in Figs. 10(b) and 10(c), and a liquid jet forms at the top of the bubble surface, piercing the lower bubble surface in Fig. 10(d). A toroidal bubble accompanied by a protrusion of the lower bubble surface forms and expands toward the rigid boundary during the rebound in Fig. 10(e) and then reaches its second maximum volume in Fig. 10(f). The computation agrees well with the experiment for a bubble collapsing and rebounding in the 500cSt silicone oil at a moderately large Reynolds number.

We then compare the computational results with the experiment<sup>57</sup> where the Reynolds number is  $Re = 6033$ . Parameters used for calculations are the same as in Fig. 4. The computational results are also re-timed for the comparisons. Figure 11 displays the bubble shapes at representative times. The computational and experimental results are shown on the left and right parts of frames (a1)–(f1), respectively. Frames (a2)–(f2) represent 2D views of the simulated bubbles, while frames (a3)–(f3) present their 3D perspectives. Figure 11(a) is for the bubble at its maximum radius when it remains spherical apart from its surface near the wall being flattened by the wall. During the late collapse stages, a liquid jet forms at the top of the bubble surface in Fig. 11(b) and impacts at the opposite bubble surface in Fig. 11(c). After the jet penetrates the bubble wall, a toroidal bubble forms, collapses continuously to its minimum volume, and rebounds in Fig. 11(d). It then reaches its second maximum volume in Fig. 11(e) and later re-collapses in Fig. 11(f).

FIG. 10. Comparison of bubble shapes between the computation and the experiment for the bubble oscillating in the 500cSt silicone oil with the viscosity being 0.485 Pa s at typical times (a) 1.90, (b) 2.66, (c) 3.16, (d) 3.42, (e) 3.67, and (f) 3.92 ms. Parameters used for the calculation are  $R_0 = 10$  mm,  $\dot{R}_0 = 12$  m/s and  $p_{b0} = 720$  Pa,  $\rho_\infty = 975$  kg/m<sup>3</sup>,  $\mu_l = 0.485$  Pa s and  $c = 950$  m/s, and the remaining parameters are the same as in Fig. 4. The left part in frames (a1)–(f1) is the computational results, while the right is the experimental results. The rigid boundary is the lower boundary of frames (a1)–(f1). The red dot displays the outer profile of the bubble shapes in the experiment. Frames (a2)–(f2) and frames (a3)–(f3) are 2D and 3D views of the simulated bubbles, respectively.

**FIG. 11.** Comparison of the bubble shapes between the computation and the experiment<sup>57</sup> at typical times (a) 65, (b) 125, (c) 130, (d) 140, (e) 185, and (f) 230  $\mu\text{s}$  during the two cycles of oscillation. The parameters used for calculation are the same as in Fig. 4. The left part in frames (a1)–(f1) is the computational results, while the right is the experimental results. The rigid boundary is the lower boundary of frames (a1)–(f1). The red dot displays the outer profile of the bubble shapes in the experiment. Frames (a2)–(f2) and frames (a3)–(f3) are 2D and 3D views of the simulated bubbles, respectively.

The computation repeats all these features observed in the experiment for the bubble expansion, collapse, rebound, and re-collapse. The computational results for the bubble shapes agree with those of the experiment during the first and second oscillation cycles. The jet is not observable in the experiments because of the reflection of light off the liquid/gas interface; nevertheless, the outer profile of the toroidal bubble of the computation has excellent agreement with that of the experiment.

Figure 12 compares the equivalent bubble radius  $R_{eq}$  history between the computation and the experiment.<sup>57</sup> The excellent agreement is shown for the first and second cycles of oscillation. The relative error of the maximum radius in the second cycle is about 7%, which may be due to the heat transfer and the phase change neglected in the model and/or the measurement errors in the experiment.

It is challenging to compute the energy loss of a bubble system associated with the emission of shockwaves at the end of the collapse. Typically, this has been handled by empirically removing a part of the

**FIG. 12.** Comparison of the equivalent bubble radius  $R_{eq}$  history between the computation and the experiment<sup>57</sup> for the case of  $Re = 6033$  in Fig. 11. The parameters used for the calculation are the same as in Fig. 4.

bubble potential energy at the end of the first cycle of oscillation.<sup>57</sup> Otherwise, subsequent numerical results are incorrect. Without resetting the rebounding condition, our computational results agree well with the experiments for the second cycle of oscillation.

**B. Bubble dynamics near a rigid boundary for  $Re = O(10)$**

In this subsection, we conduct numerical simulations of bubble dynamics near a rigid boundary for a Reynolds number of  $O(10)$  and study the viscous effects on bubble dynamics near a rigid boundary. We will re-compute the case in Fig. 11 for  $Re = 6033$  by setting  $Re = 75$  (with  $\mu_l = 0.08 \text{ Pa} \cdot \text{s}$ ), with all other parameters kept unchanged.

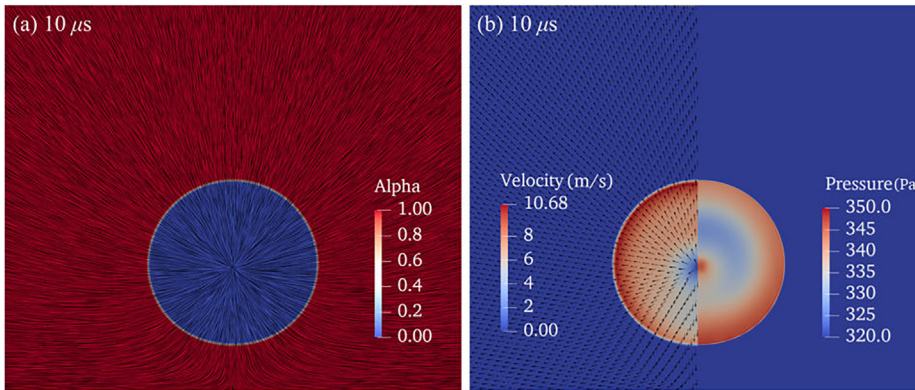

**1. Vortex ring development**

Figure 13 displays the streamlines and velocity vectors outside and inside the bubble and the velocity and pressure contours inside the bubble. When the bubble is nearly spherical, a stagnation point exists at the center of the bubble, from which the streamlines radiate outward, as shown in Fig. 13(a). The part of the bubble surface furthest from the wall expands faster than the closer part, as the latter is hindered by the wall. Consequently, the airflow above the stagnation point moves faster than the airflow below the stagnation point, and the airflow above the stagnation point has smaller pressure, as shown in Fig. 13(b). This is consistent with the Bernoulli equation.

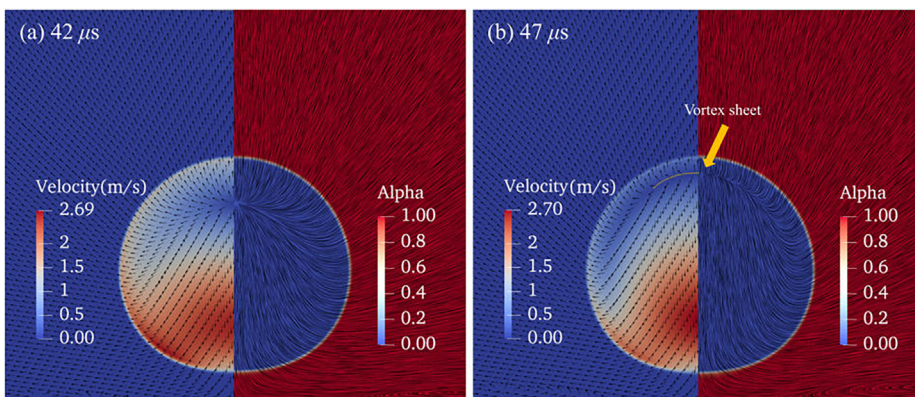

As a result of the pressure gradient, the stagnation point moves away from the wall along the axis of symmetry during expansion. Two kinds of streamlines form: concave shape for the upper part and convex shape for the lower part, as shown in Fig. 14(a). The streamlines are becoming denser closer to the upward-moving stagnation point. The concave and convex streamlines tend to converge at the stagnation point with different velocities, and the strong velocity difference leads to the formation of the vortex sheet near the upper bubble surface as shown in Fig. 14(b).

The vortex sheet subsequently approaches the bubble interface and begins transferring momentum to the gas-liquid interface, which

**FIG. 13.** (a) Streamlines, (b) velocity vectors (left), velocity contour (left), and pressure contour (right) during early expansion when the bubble is nearly spherical. The Reynolds number is  $Re = 75$  ( $\mu_l = 0.08$  Pa s), and the remaining parameters are the same as in Fig. 4.

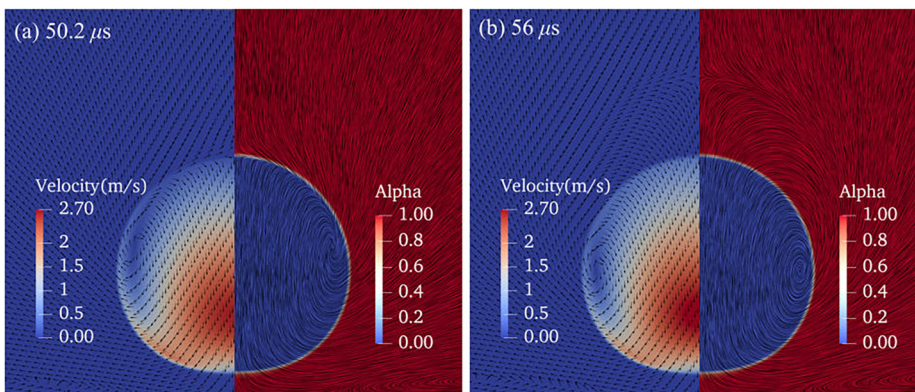

**FIG. 14.** Velocity vectors (left in each figure), velocity contours (left in each figure), and streamlines (right in each figure) at (a) 42 and (b) 47  $\mu$ s showing the formation of the vortex sheet generated from the bubble collapse near a rigid boundary for the case of  $Re = 75$  in Fig. 13. (Recall that the simulations are axisymmetric when visualizing the 3D form of the vortex sheet).

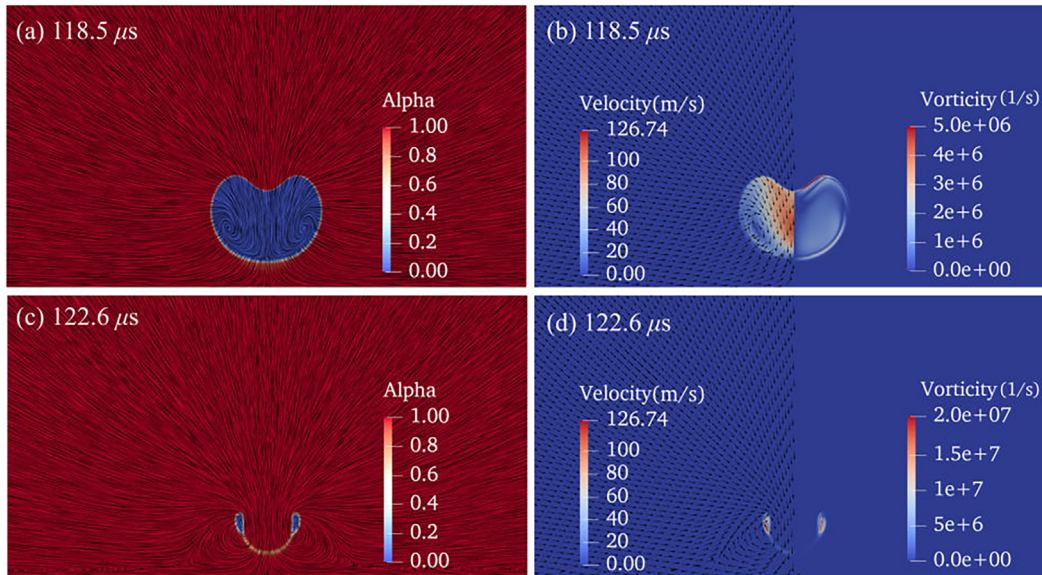

in turn influences the flow in the liquid close to the bubble wall. At approximately the moment the bubble achieves maximum volume, the stagnation point meets the bubble surface in Fig. 15(a) and moves out of the bubble afterward in Fig. 15(b). The part of the vortex sheet within the bubble decays after it meets with the interface, where it is subject to the much higher shear stress from the liquid with a much higher viscosity than gases. Due to the higher pressure zone at the stagnation point, the liquid flow above it is stopped, the part of the bubble surface furthest from the wall collapses first, and the receding bubble surface drags the surrounding liquid toward it, as observed by Lechner

*et al.*<sup>53</sup> In the meantime, the part of the bubble surface nearest to the wall still expands, pushing the liquid between the bubble and rigid boundary outward. This generates a circulation around the periphery of the cross section of the bubble. A vortex ring is accordingly generated within the bubble gas at the outer rim of the vortex sheet.

During the collapse phase, the distal part of the bubble surface from the wall collapses faster, the surrounding liquid flow toward the distal part strengthens, and the vortex ring intensifies, as shown in Figs. 16(a) and 16(b). These three events enhance each other during collapse, forming a positive feedback loop. A high-speed liquid jet

**FIG. 15.** Velocity vectors (left in each figure), velocity contours (left in each figure), and streamlines (right in each figure) at (a) 50.2 and (b) 56  $\mu$ s showing the conversion from the vortex sheet to the vortex ring for the case of  $Re = 75$  in Fig. 13.

**FIG. 16.** Streamlines [(a) and (c)], velocity vectors [left in (b) and (d)], velocity contours [left in (b) and (d)], and vorticity contours [right in (b) and (d)] showing the further development of the vortex ring after generation during bubble collapse for the case of  $Re = 75$  in Fig. 13.

develops, and it gets accelerated by the vortex ring at the bubble surface, which subsequently penetrates the bubble, from which it is redirected outward after impacting on the wall as shown in Figs. 16(c) and 16(d). This strengthens the circulation around the vortex ring even further.

With the core of the vortex ring inside the bubble gas, much less energy loss occurs than inside the liquid. This is because the energy dissipation of a vortex ring is proportional to viscosity, and most of the energy dissipation occurs near its center.<sup>87</sup> With its core inside the bubble gas, the vortex ring accelerates the jet like a bearing system.

The vortex ring associated with a toroidal bubble has been an essential topic for bubble dynamics and plays a key role in toroidal bubble dynamics.<sup>36,41,88–91</sup> With the concept of ideal fluid mechanics, the generation of the vortex ring is attributed to the topological transform of the liquid domain after the bubble jet penetrates through the bubble. Here, we have revealed that the generation process of the vortex ring takes place within the bubble gas before the bubble jet penetrates through the bubble.

The results on the vortex sheet and the vortex ring provide two mechanisms for the nanodroplet injection model.<sup>60,61</sup> Both the decay of the vortex sheet as it interacts with the bubble interface and the vortex ring adjacent to the bubble interface are potential sources of nanodroplets in the hot bubble gas.

## 2. Bubble oscillation and jetting

As shown in Fig. 17, the bubble expands without significant change to the maximum volume from Figs. 17(a) and 17(b) for the two Reynolds numbers. At the larger Reynolds number, the jet forms earlier in Fig. 17(c) and develops to a larger and sharper jet in Fig. 17(d). When the jet impacts the opposite bubble surface in Fig. 17(d), the jet at the larger Reynolds number is nearer to the rigid

boundary. Similar viscous effects on bubble shapes were observed by Minsier *et al.*<sup>49</sup> The bubble for  $Re = 6033$  rebounds to a larger maximum volume as shown in Fig. 17(e).

In Fig. 18(a), the equivalent bubble radius  $R_{eq}$  histories are compared for the two Reynolds numbers:  $Re = 75$  and  $Re = 6033$ . The first cycle experiences a marginal reduction in both the maximum bubble radius and period at  $Re = 75$ , attributed to viscous dissipation. For  $Re = 75$ , a smaller jet is formed in Fig. 17(d), leading to an increase in the kinetic energy associated with the collapse process. Following the more intense collapse, a greater amount of energy is dissipated through the emission of shockwaves toward the end of the collapse. Consequently, the bubble rebounds to a much smaller maximum radius and period during the second cycle at  $Re = 75$ .

Figure 18(b) shows the jet velocity  $V_{jet}$  histories with the time counted from the jet starting ( $t = 114 \mu\text{s}$  for  $Re = 6033$  and  $t = 116 \mu\text{s}$  for  $Re = 75$ ) in Fig. 17(c) to the jet impacting on the opposite bubble wall ( $t = 122 \mu\text{s}$  for  $Re = 6033$  and  $t = 123 \mu\text{s}$  for  $Re = 75$ ) in Fig. 17(d). For  $Re = 6033$ , the jet velocity first increases with time and then reaches a nearly constant value, which was also observed by Minsier *et al.*<sup>49</sup> However, for  $Re = 75$ , the jet velocity increases continuously before impacting at the opposite surface, and it attains a larger value than for  $Re = 6033$ .

## 3. Shockwave emission and pressure on the wall

Shockwaves are emitted at the end of collapse and are associated with significant energy loss of the bubble system.<sup>37</sup> The shockwaves are believed to be the leading cause of the erosion of the rigid boundary.<sup>17,92</sup> The pressure contours in Fig. 19 display the emission and propagation of shockwaves for  $Re = 75$ . A ring shockwave emits from the bubble ring at the end of the collapse in Fig. 19(a), propagates with a circular cross section in Fig. 19(b), and impacts itself at the axis of

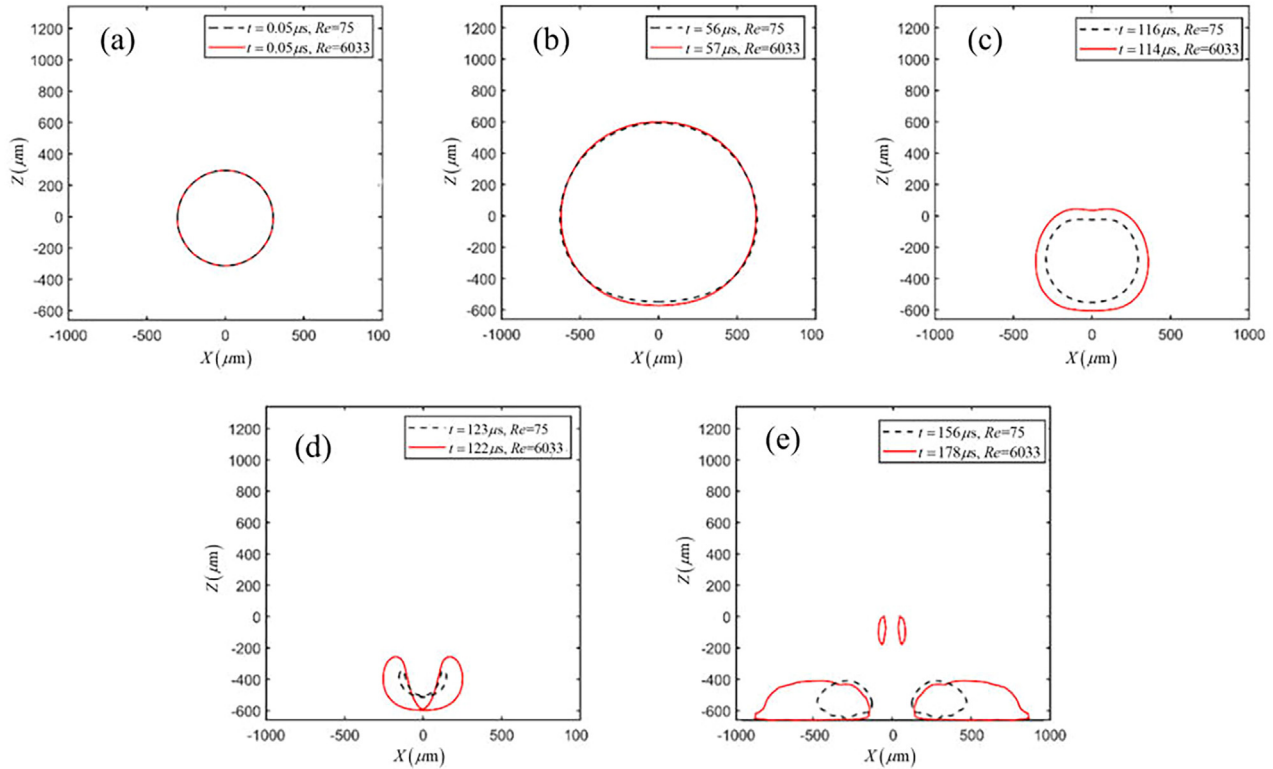

FIG. 17. Bubble shapes evolutions near a rigid boundary for  $Re = 75, 6033$  ( $\mu_l = 0.08, 0.001$  Pa s, respectively). The remaining parameters are the same as in Fig. 4.

symmetry resulting in a higher pressure in Fig. 19(c). As a result of the further propagation of the shockwaves, two intersection points exist on the symmetry axis where the pressure is higher in Fig. 19(d). The two intersection points move in opposite directions in Fig. 19(e), and a high-pressure region forms when the shockwaves reach the rigid boundary. Subsequently, a clear reflection moving away from the rigid boundary can be observed in Fig. 19(f). Similar phenomena were observed by Lechner *et al.*<sup>53</sup>

Figure 20 shows the pressure on the center point of the rigid boundary (green spots in Fig. 19) as a function of time for  $Re = 75, 6033$ . The stronger collapse at  $Re = 75$  leads to the stronger shockwave emission, and thus, the pressure on the rigid boundary is also larger. However, the shockwaves are much weaker, and the pressure on the rigid boundary is much smaller at the end of the second cycle for  $Re = 75$  due to greater energy loss at the end of the first cycle of oscillation.

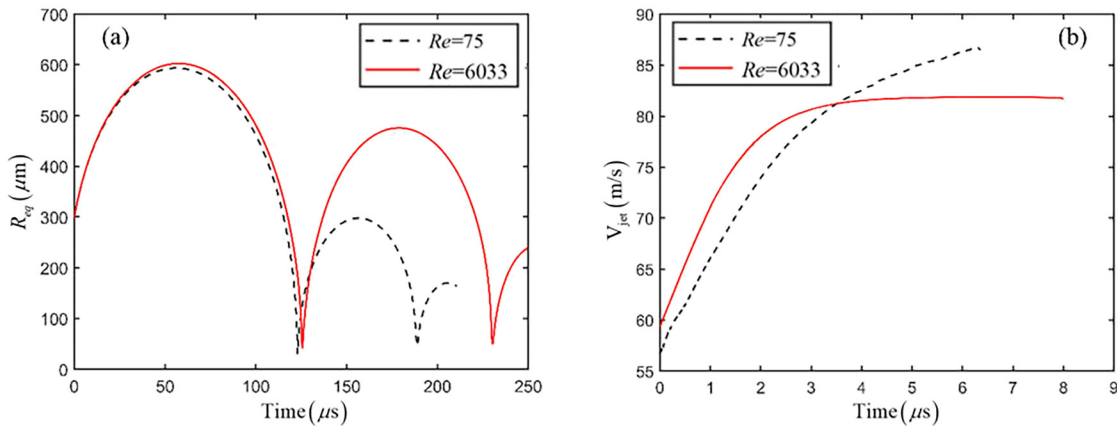

FIG. 18. Numerical results for  $Re = 75, 6033$  ( $\mu_l = 0.08, 0.001$  Pa s, respectively): (a) histories of the equivalent bubble radius  $R_{eq}$  and (b) the jet velocity  $V_{jet}$  with the time counted from the jet starting ( $t = 114 \mu s$  for  $Re = 6033$  and  $t = 116 \mu s$  for  $Re = 75$ ). The remaining parameters are the same as in Fig. 4.

FIG. 19. Pressure contours showing the emission and propagation of shockwaves generated at the end of the first bubble collapse for the case of  $Re = 75$  in Fig. 13.

4. Shear stress on the rigid boundary

Figure 21 shows the spatial-temporal distribution of the shear stress  $\tau$  on the rigid boundary for  $Re = 75$ , using  $\log_{10}|\tau|$  due to its large range of values. The direction pointing away from the axis of symmetry is defined as positive and plotted in red. The direction pointing to the axis of symmetry is negative and plotted in blue. As the bubble expands, it drives the liquid outward, and the shear stress at the wall is outward. Starting from the late stages of expansion for  $t \geq 40 \mu s$ , the shear stress turns inward far away from the axis of symmetry.

FIG. 20. Pressure on the center point of the rigid boundary (green spots in Fig. 19) as a function of time for  $Re = 75, 6033$  ( $\mu = 0.08, 0.001$  Pa s, respectively). The remaining parameters are the same as in Fig. 4.

The transition from outward to inward shear stress corresponds to the stagnation ring.

The mechanism of the stagnation ring is explained as follows. Figure 22 shows the flow field distribution at  $t = 42 \mu s$  when the bubble is at the late stages of expansion. At certain late stages of expansion, the bubble gas pressure is lower than the hydrostatic pressure. The liquid around the bubble moves outward owing to its inertia, and the part of the liquid near the wall has less velocity because of the shear stress of the wall. Therefore, the reversed flow toward the center starts near the wall, far away from the axis of symmetry before the end of the expansion, resulting in the stagnation ring occurring before the end of the expansion.

The stagnation ring exists over the wall, with its radius decreasing as the bubble further expands and then collapses. During the late collapse and before rebound for  $95 \mu s \leq t \leq 120 \mu s$ , the shear stress is negative everywhere on the boundary and reaches its maximum absolute value. This is generated by the fast-shrinking bubble.

The above feature is repeated during the second cycle of oscillation. During a large part of the rebounding, the shear stress is outward everywhere due to the fast-spreading jet along the boundary, and a stagnation ring occurs during the later stages of the rebound, with its radius decreasing with time. However, the shear stress distribution is complex and changes rapidly due to the complex flow field caused by the toroidal bubble collapse at the end of the second cycle. The above phenomena were also observed by Zeng *et al.*<sup>57</sup>

Figure 23 shows the time histories of the shear stress at a probe point on the rigid boundary  $180 \mu m$  from the axis of symmetry (green spots in Fig. 24). For both cases, a distinct impulse with a greater magnitude and a shorter period is evident, along with a more gradual impulse characterized by a smaller magnitude and a longer period. The shear stress for  $Re = 75$  is larger than that for  $Re = 6033$ .

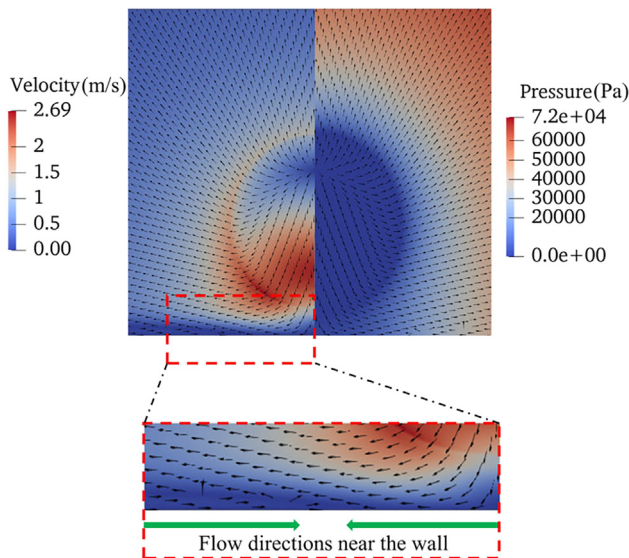

**FIG. 21.** The time-space map of the wall shear stress for the case of  $Re = 75$  in Fig. 13. The logarithm to the base 10 is taken of the wall shear stress values before plotting due to the large range of values. The first color bar represents the positive wall shear stress (away from the axis of symmetry), while the second one represents the negative wall shear stress. Overlaid is the bubble dynamics as a dashed line adapted from Fig. 18(a).

Figure 24 displays the bubble shapes and the flow fields for  $Re = 75$  at different times during collapse and rebound, where the probe point is marked as green spots. Figure 24(a) is at  $t = 120 \mu s$  when the shear stress is negative and small at the probe point. Figure 24(b) is at  $t = 123 \mu s$  when the shockwaves impact the probe point, resulting in the sharp impulse of shear stress in Fig. 23. Figure 24(c) is at  $t = 127 \mu s$ , corresponding to the milder impulse of shear stress in

Fig. 23, when the jet is spreading along the wall after impacting on the rigid boundary. At  $t = 150 \mu s$  in Fig. 24(d), the jet is still spreading, but the magnitude is much smaller, which corresponds to the decreasing wall shear stress in Fig. 23.

In conclusion, when a bubble undergoes inertial collapse near a rigid boundary, significant shear stress emerges primarily during the propagation of the shockwaves along the boundary and the spread of

**FIG. 22.** Velocity vectors (black arrows), velocity contour (left), and pressure contour (right) at  $t = 42 \mu s$  for the case of  $Re = 75$  in Fig. 13.

**FIG. 23.** The time histories of the shear stress at a point on the rigid boundary, at  $180 \mu m$  from the axis of symmetry, for  $Re = 75, 6033$  ( $\mu_l = 0.08, 0.001 Pa s$ , respectively). Other parameters are the same as in Fig. 4.

**FIG. 24.** Bubble shapes [frames (a1)–(d1)] and flow fields [frames (a2)–(d2)] including velocity vectors [left in frames (a2)–(d2)], velocity contours [left in frames (a2)–(d2)] and pressure contours [right in frames (a2)–(d2)] at (a) 120, (b) 123, (c) 127, and (d) 150  $\mu\text{s}$  during bubble collapse and rebound for the case of  $Re = 75$  in Fig. 13.

the jet along the boundary. The former has a much higher amplitude, and the latter has a longer period. They both increase with decreasing Reynolds number.

**V. SUMMARY AND CONCLUSIONS**

Bubble dynamics near a rigid boundary for Reynolds number  $O(10-100)$  are studied experimentally using high-speed photography of spark-generated bubble oscillation in silicone oils, whose viscosities are about three orders larger than water. They have also been studied numerically by solving the compressible Navier–Stokes equations by extending the open-source code OpenFOAM. A non-reflective boundary

condition at the far field is proposed based on the asymptotic behavior, which allows for a tenfold reduction in the size of the computational domain. New dynamic features are revealed.

**A. Mechanisms underlying the bubble jetting and vortex ring**

During expansion, the distal part of the bubble surface from the wall expands faster than the closer part, as the latter is hindered by the wall. Accordingly, the bubble gas on the distal side flows faster away from the stagnation point, initially at the bubble center, and has

18 December 2023 16:06:50

smaller pressure according to the Bernoulli equation. As a result, the stagnation point moves away from the wall during expansion, and a vortex sheet forms inside the bubble as the streamlines converge to the stagnation point with different velocities.

As the vortex sheet approaches the bubble interface, it transfers momentum to the gas–liquid interface, influencing the liquid flow close to the bubble wall. At approximately the maximum bubble volume, the stagnation point moves out of the bubble. The high-pressure zone at the stagnation point drives the distal bubble surface to collapse first and fastest, pulling the side liquid inward, as observed by Lechner *et al.*<sup>53</sup> In the meantime, the part of the bubble surface nearest the wall still expands, pushing the liquid between the bubble and the rigid boundary outward. This generates a circulation around the side cross section of the bubble. A vortex ring is accordingly generated within the bubble gas at the outer rim of the vortex sheet as the vortex sheet decays, owing to the higher shear stress from the liquid.

The distal bubble surface collapses faster during the collapse, the liquid flow toward the distal part strengthens, and the vortex ring intensifies. These events enhance each other in a positive feedback loop. A high-speed liquid jet develops at the distal bubble surface, accelerated by the vortex ring. The liquid jet subsequently penetrates the bubble and is redirected outward after impacting the wall. This in turn strengthens the circulation around the vortex ring.

With the core of the vortex ring inside the bubble gas, much less energy loss occurs than inside the liquid. This is because the energy dissipation of a vortex ring is proportional to viscosity, and most energy dissipation occurs near its center. With its core inside the bubble gas, the vortex ring accelerates the jet like a bearing system. These new insights into the gas flow inside the bubble provide supporting evidence for the nanodroplet injection model.

## B. Viscous effects

The jet is shallower due to viscosity effects and has less kinetic energy at a smaller Reynolds number, as observed by Minsier *et al.*<sup>49</sup> With less kinetic energy associated with the jet, the bubble collapses violently to a smaller minimum value, producing stronger shockwaves. With significantly more energy radiated due to the stronger shockwaves, the subsequent oscillation during the second cycle has a smaller maximum radius. The period of oscillation is energy dependent; therefore, the period also reduces due to the energy reduction.

The pressure on the wall is more significant due to the stronger shockwave emission at the end of the first cycle when the Reynolds number is smaller. As more energy is radiated due to stronger shockwaves at the end of the first cycle, the shockwaves are much weaker, and the pressure on the rigid boundary is much smaller at the end of the second cycle.

An oscillating bubble in a higher viscous liquid is more stable. A bubble often breaks up after the first cycle of oscillation in water. A bubble often remains stable in higher viscosity liquid after multiple oscillation cycles.

For a bubble in inertial collapse near a rigid boundary, the significant shear stress at the boundary occurs primarily as the shockwaves propagate and the jet spreads along the boundary. The former has a much higher amplitude, and the latter has a longer period. They both increase with decreasing Reynolds number.

## ACKNOWLEDGMENTS

The computations described in this paper were performed using the University of Birmingham's BlueBEAR HPC service, which provides a high-performance computing service to the University's research community. See <http://www.birmingham.ac.uk/bear> for more details. Valuable discussions were carried out with Dr. Cary Turangan, Institute of High Performance Computing, Singapore.
