Abstract

The purpose of this study was to investigate the prevalence of three sarcopenia definitions and their associations with fracture risk in a population of older Swedish women when adjusted for FRAX-based risk factors. 2,883 women 77.8 years (mean) old were included. Sarcopenia was defined based on the Sarcopenia Definitions and Outcomes Consortium (SDOC; low handgrip strength and gait speed), revised European Working Group on Sarcopenia in Older People (EWGSOP2; low appendicular lean mass index (ALM, appendicular lean mass/height (kg/m^2)), and hand grip strength (kg)) and Asian Working Group for Sarcopenia (AWGS; low ALM, and hand grip strength (kg)) definition. Femoral neck T-score was obtained from dual-energy X-ray absorptiometry. All fractures, confirmed by X-ray or medical record review, were subsequently categorized as major osteoporotic fractures (MOF) and hip fractures. Deaths were verified through regional registers. The total follow-up time was 6.4±1.3 (mean±SD) years. Cox regression (hazard ratios (HR) and 95% confidence intervals (CI)) analyses were performed adjusted for age, fracture risk assessment (FRAX) variables and femoral neck T-score. Sarcopenia prevalence was 4.5% (n=129) according to SDOC, 12.5% (n=360) for EWGSOP2 and 10.3% (n=296) defined by AWGS. Individuals with sarcopenia defined by SDOC had a higher mortality risk than individuals without sarcopenia (HR: 3.41; 95% CI: 2.51, 4.62) after adjusting for age and FRAX variables. Sarcopenia according to EWGSOP2 and AWGS was not associated with an increased fracture risk after adjusting for age and FRAX variables. Individuals with sarcopenia defined by SDOC had a higher risk for any fractures (HR: 1.48; 95% CI: 1.10, 1.99) and MOF (HR: 1.42; 95% CI: 1.03, 1.98) compared with

4

individuals without sarcopenia after adjusting for clinical risk factors used in FRAX. In conclusion, sarcopenia defined by SDOC, incorporating muscle function/strength, was the only sarcopenia definition associated with fracture risk in older women.

Lay Summary

This study aimed to investigate the risk of sarcopenia on fracture risk in older Swedish women. Data was utilized from 2,883 women aged 75 to 80 years in the Swedish SUPERB cohort. Sarcopenia was defined using three different definitions including the Sarcopenia Definitions and Outcomes Consortium (SDOC) which includes grip strength and gait speed, while the revised European Working Group on Sarcopenia in Older People (EWGSOP2) and the Asian Working Group for Sarcopenia (AWGS) definition includes appendicular lean mass index (ALMI) measured by dual-energy X-ray absorptiometry (DXA) and grip strength.

The results demonstrated that SDOC-defined sarcopenia was associated with a higher mortality risk, with increased risk of any fractures, and major osteoporotic fractures whereas the EWGSOP2 and AWGS definitions were not associated with fracture risk. In summary, the study demonstrates that sarcopenia defined by SDOC, considering muscle function and strength, rather than ALMI, was the only investigated sarcopenia definition associated with fracture risk.

Introduction

Osteoporosis is a common condition among older adults and is characterised by low bone mineral density (BMD) and deterioration of bone microarchitecture leading to increased

5

risk of fractures.[1-3] Fractures in the ageing population markedly increase the risk of hospitalisation, morbidity and mortality posing a significant financial burden to society, in addition the negative impact on population health.[4,5]

Sarcopenia is a condition defined as an age-associated loss of skeletal muscle mass and function.[6-8] Sarcopenia is associated with several adverse health outcomes including functional decline, immobility, falls and fractures, hospitalisation and mortality.[9-14] Clinical recognition of sarcopenia among older adults is limited due to the lack of a single universally accepted operational definition making it difficult for clinicians to diagnose and treat this condition[10,11,15] The prevalence of sarcopenia varies widely as it is dependent upon several factors including age, sex, ethnicity, definition and diagnostic criteria applied.[13,16-18] In a recent study of Swedish older adults, the prevalence of sarcopenia defined by the European Working Group on Sarcopenia in Older People (EWGSOP) and revised EWGSOP definitions ranged between 1.4 to 7.8% in those aged 70 years and 42 to 62% in those aged 85 years.[8,16,19] Recent studies have demonstrated concerns over the predictive capacity of dual x-ray absorptiometry (DXA) determined appendicular lean mass (ALM) on several health outcomes such as falls and fractures.[20,21] Although, several definitions with various cut-points of muscle mass and/or muscle function have been previously proposed, no studies have investigated the associations between several sarcopenia definitions and fracture risk in a population of older women. [8,9,19,22]

With an increase in the age of the population and the prevalence of sarcopenia and osteoporosis, the incidence and rate of fractures is markedly increasing.[23] In particular, the incidence of hip fractures in Swedish women is the highest among the world but whether the presence of sarcopenia exacerbates the risk of fractures has been insufficiently investigated.[24] Previous studies have yielded inconsistent results, with some, but not others, have found associations between sarcopenia according to the Asian Working Group for Sarcopenia

6

(AWGS), EWGSOP and fracture.[25] Furthermore, there is a notable scarcity of studies examining the relationships between fractures at various sites and multiple definitions of sarcopenia within a single cohort.[26] Recent evidence suggests that the clinical characteristics and poor health outcomes among individuals with sarcopenia makes it a critical indicator of higher fracture risk.[9,27,28] It is therefore necessary to determine if assessments of sarcopenia components should be included as part of the fracture prevention tools for early diagnosis, treatment and to reduce the risk of subsequent consequences associated from this condition such as hospitalisation and mortality.

This study aimed to investigate the prevalence of sarcopenia and to determine associations of various sarcopenia definitions with fracture risk in a population of Swedish older women, including adjustment for FRAX-based risk variables.

Methods

Study design and participants

Data from the Sahlgrenska University Hospital Prospective Evaluation of Risk of Bone Fractures (SUPERB) study, a prospective population-based study of 3,028 older women residing in the greater Gothenburg area, Sweden, were utilised for this analysis. Participants aged between 75 to 80 years were recruited from the Swedish national population register. Participants were excluded from this study if they were unable to walk with or without supportive walking aids, understand Swedish, and have at least one hip that could be evaluated for areal bone mineral density (aBMD) determined by the dual energy X-ray absorptiometry (DXA). The total follow-up time was 6.4±1.3 (mean±SD) years. This study was approved by the regional Ethics Review Board in Gothenburg, and all study participants provided written informed consent.

7

Questionnaires

Participants completed self-administered questionnaires including questions on physical activity.

Ten-year probabilities of major osteoporotic and hip fractures were calculated by the FRAX tool (https:frax.shef.ac.uk/FRAX/) using self-reported information on clinical risk factors (CRFs) based on medical history, prior fractures (after the age of 50 years, excluding face and skull fractures), current smoking, parental history of hip fracture, oral glucocorticoids in doses of at least 5mg per day of prednisolone or equivalent for ≥3 months, diabetes, rheumatoid arthritis, and high alcohol consumption (3 standard measures of alcohol per day or more). FRAX scores were calculated with and without areal bone mineral density (aBMD) of the femoral neck along with all CRF's except for secondary osteoporosis which does not contribute to the calculations of fracture risk when aBMD is included [4].

Incident fractures

Incident fractures were verified by radiograph, with radiology reports retrieved from the regional digital X-ray archive. Research nurses reviewed all radiology reports examined from the baseline visit (March 2013 until May 2016). Radiographs without any record of radiology reports or uncertainty in the diagnosis of fractures, underwent a formal review by an orthopedic surgeon. The follow-up time consisted of time from the baseline exam to the first fracture (per category) and was censored for the end of the study (July 31st, 2021) and death. Fractures were categorized into hip fractures and major osteoporotic fractures for any fractures which occurred at the vertebrae, hip, proximal humerus, or the proximal femur.[29] Fractures of the skull, fingers, and toes were excluded from any fractures.

Anthropometry

8

Weight (kg) was measured to the nearest 0.1 kg using an electronic scale and body height, was measured with a standardized wall-mounted stadiometer, two consecutive times. If the two height measurements differed by ≥ 5 mm, a third measurement was performed. An average of the two height measurements, or the two most similar measurements if three were taken, was used. Height (m) was measured to the nearest cm using a wall-mounted calibrated stadiometer with footwear and heavy items of clothing removed. BMI was calculated as weight/height (kg/m^2).

Physical function

Hand grip strength was measured using a hydraulic dynamometer (Saehan dynamometer, model SH5001, Saehan Corporation, Masan, Korea), as previously described.[30] In summary, participants gripped the dynamometer with maximal force in a seated position. Participants repeated this measurement twice in both arms with a 30-seconds rest between trials and the mean force of the dominant hand from the two trials was used to calculate average hand grip strength. Gait speed was performed twice and was measured over a 10-metre distance. To prevent the effects of acceleration and deceleration only the middle six metres distance was utilised to calculate the average gait speed (m/s). Participants also completed a chair stand test where they were instructed to stand up straight from a seated position and sit down as many times as possible within 30 seconds with their arms across their chest. A slow chair stands time (>15 seconds for five rises) was calculated using the number of stands per second over 30 seconds and then selecting those who needed >15 seconds to do five chair stands.

Dual-energy X-ray absorptiometry (DXA)

Whole-body DXA scans measured body composition parameters including body fat percentage and lean mass using Hologic Discovery A (S/N 86491, Waltham, MA, USA) for n=2,995 participants and owing to machine failure n=33 scans were performed using another Hologic Discovery A device. Appendicular lean mass (ALM) was calculated as the sum of lean mass in the upper- and lower-limbs. DXA scans were also used to measure aBMD at the non-dominant total hip, femoral neck, lumbar spine and whole-body. The coefficient of variation (CV) for aBMD was 0.7% at the femoral neck and 1.3% at the lumbar spine at our centre.

Sarcopenia definitions

Three of the most commonly and recently developed sarcopenia definitions were utilized to compare differences in the prevalence of sarcopenia in this group of older women and to determine associations with fracture risk. Sarcopenia was defined using the Sarcopenia Definitions and Outcomes Consortium (SDOC),[22] revised European Working Group on Sarcopenia in Older People (EWGSOP2) [8] definitions, and the revised Asian Working Group for Sarcopenia (AWGS) definition.[31] SDOC definition utilises low hand grip strength (<20kg) and low gait speed (<0.8m/s).[22] EWGSOP2 definition utilises low appendicular lean mass index (ALMI) (<5.5kg/m^2 for women) and low hand grip strength (<16kg for women) or slow chair stands time (>15 seconds for five rises).[8] AWGS definition utilises low ALMI (<5.4 kg/m^2) and low hand grip strength (<18 kg) or low gait speed (0.8m/s).[31] Information for one or more variables used in these sarcopenia definitions was unavailable for 145 women, resulting in n=2,883 women in the present study.

Statistical analysis

All data analyses were performed using SPSS Statistics 25 (IBM, NY, USA). Participant characteristics were reported as mean and standard deviations for continuous

10

variables, or as percentages for categorical variables. Independent samples t-tests or X^2 tests were performed to compare means between individuals with and without sarcopenia. Cox regression analysis was performed to investigate the associations between three frequently used sarcopenia definitions (SDOC, EWGSOP2 and AWGS), mortality risk and fracture risk (any fractures, major osteoporotic fractures and hip fractures).[8,19,22,31] The Cox assumption of proportional hazards was tested using graphical methods and the observed relative hazards remained constant over time.

Statistical imputation was performed for missing CRFs variables (198 (6.7%) women had missing data on one CRF) using the MICE-package in R-Studio (Multivariate imputation by Chained Equations), using a single imputation with 10 iterations. In addition to the fracture outcomes, all the other CRFs were included in the imputation. Similar frequencies of CRFs were observed before and after imputation (Supplemental Table 1 and Table 1).

Incidence per 1000 person-years was calculated as number of events divided by total follow-up time (until fracture, death or censored) per 1000 years. Adjustment for CRFs included age, BMI, other FRAX variables and femoral neck T-score. In addition, to assess the implications of death as a competing risk, the Fine and Gray sub-distributed hazard for fracture was compared between individuals with/without sarcopenia using the stcrreg command in Stata 17.0.[32]

For all analyses, $p<0.05$ or 95% confidence intervals not including the null point was considered statistically significant.

Results

In total, 2,883 older women with the mean age of 77.8 years were included in this study. Prevalence of sarcopenia varied based on the sarcopenia definitions with the highest among older women when sarcopenia was defined by the EWGSOP2 definition (12.5%), followed by AWGS (10.3%), with the lowest prevalence by the SDOC definition (4.5%) (Table 1). A higher

11

proportion of individuals based on the SDOC definition had low hand grip strength compared to when defined by EWGSOP2 and AWGS definitions (Supplemental Table 2).

Women with sarcopenia defined by SDOC definition had the highest proportion of incident fractures including any fractures, major osteoporotic fractures and hip fractures (37.2%, 30.2% and 9.3%, respectively; Table 2). In addition, sarcopenia defined by SDOC definition was the only definition that was associated with all the fracture outcomes, although the association with hip fracture only reached significance in the unadjusted model (Table 2). For those with SDOC-defined sarcopenia, the risk of any fractures was increased by 48% and the risk of major osteoporotic fractures by 42%, in fully adjusted models. In contrast, sarcopenia defined by the AGWS definition was not associated with any fractures, major osteoporotic fracture, or mortality (all *p*>0.05; Table 2), whilst an increased risk for hip fracture was observed, but only in an unadjusted model. Sarcopenia defined by the EWGSOP2 definition was also not associated with the risk of fracture (Table 2). Intriguingly, it was associated with a 24% lower risk of major osteoporotic fractures compared to individuals without sarcopenia after adjusting for clinical risk factors and BMD (Table 2).

The distribution of CRF prevalence did not differ between those with and without sarcopenia, with the exception for women with SDOC in whom rheumatoid arthritis and smoking was more common (Table 1). Frequencies of CRFs according to sarcopenia definition was similar in complete cases (without imputations; Supplemental Table1).

During follow-up, the mortality risk among individuals with sarcopenia defined by the SDOC definition was the highest (38.0%), followed by the EWGSOP2 definition (16.1%) with the lowest by the AWGS definition (15.5%). After adjusting for CRFs and femoral neck T-score, individuals with sarcopenia defined by SDOC had 3.4 times greater mortality risk compared to individuals without sarcopenia (Table 2).

12

An analysis considering the competing risk of mortality according to Fine and Gray, demonstrated that when sarcopenia was defined by the SDOC definition it was associated with any fractures and major osteoporotic fracture in the models adjusted for CRFs and femoral neck T-score ($p<0.05$), although the association with hip fracture was only significant in models adjusted for age and CRFs (Table 3). None of the other sarcopenia definitions were associated with fracture risk in Fine and Gray models, adjusted for age and CRFs (Table 3).

Discussion

In this population of older adults, sarcopenia defined by SDOC was the only definition associated with fractures and mortality risk but at low population prevalence. In addition, both the EWGSOP2 and AWGS sarcopenia definitions failed to be associated with fractures and mortality in this population of older women. These results indicate that fracture prediction methods in older women may be improved by assessing physical performance and/or muscle strength, but that such assessment will only affect a small proportion of those investigated.

Prevalence of sarcopenia varied largely according to individual definitions, again highlighting the difficulties with the operationalization of sarcopenia definitions in clinical practice and impeding the diagnosis and treatment of this condition among older adults. Sarcopenia definitions have differential associations with adverse health outcomes including fractures.[33-35] In the current study, sarcopenia defined by SDOC was consistently associated any fractures and major osteoporotic fractures. Likewise, in a study of 10,411 men aged 65 years or more, SDOC definition was associated with fracture outcomes.[9] Similarly, a study including 13,421 community-dwelling men and 4,282 women aged 65 years and older demonstrated that both components of SDOC definitions including low hand grip strength and gait speed were associated with a higher risk of adverse health outcomes including hip fractures.[36] In contrast, in the current study, SDOC definition was not significantly associated

13

with hip fractures in models adjusted for CRFs and femoral neck T-score, but the lack of significant association was likely due to low statistical power for that specific analysis. In addition, in the current study, the SDOC definition was significantly associated with an increased risk of any fractures and major osteoporotic fractures. Sarcopenia is therefore an important risk factor for fractures in this population of older women, even when considering the risk of death. As a result, the cost-effective and feasible nature of assessing muscle strength and/or physical function along with its association with fractures indicates the importance of incorporating these measures into sarcopenia definitions and part of the fracture prediction tools.[37,38] The low prevalence of SDOC defined sarcopenia in the SUPERB-cohort, is in agreement with low prevalence numbers seen in other similar cohorts of older adults.[14]

Importantly, the SDOC definition in the current study population identified individuals with severe functional limitations, as reflected by significantly lower gait speeds compared to sarcopenic groups defined by the EWGSOP2 and AWGS definitions. This therefore suggests that sarcopenia defined by the SDOC definition may capture individuals with poor physical function attributable to factors beyond age-related muscle wasting, potentially implicating muscle quality, including muscle fat infiltration which may potentially explain the increased risk of fractures in the current study.[39]

Sarcopenia definitions including DXA-determined ALM are not associated with fractures in older adults.[9,40] In the current study, both EWGSOP2 and AWGS sarcopenia definitions were not associated with increased fracture risk. A recent study including 10,411 men aged 65 years and older demonstrated that the EWGSOP2 severe sarcopenia definition including poor muscle strength, muscle mass, and physical performance was associated with a higher risk of major osteoporotic fractures after adjusting for CRFs including age, follow-up time, and falls or FRAX major osteoporotic fracture probability with BMD or femoral neck T-score.[9] This contrasts with the current study findings, in which EWGSOP2 sarcopenia

14

definition had a 24% lower risk of major osteoporotic fractures but was not associated with hip or any fractures after adjusting for CRFs and femoral neck T-score. It is possible that DXA-determined ALM diminishes the associations between sarcopenia definitions and fractures although the findings for major osteoporotic fractures in the current study are unclear.[9,41] However, these associations were likely affected by competing risk of death, supported by the lack of association between sarcopenia defined by EWGSOP2 and fracture outcomes in the Fine and Gray analysis. In addition, it is possible that measures of muscle strength/function are closely associated with biomechanical factors that contribute to falls and fractures such as balance, coordination, and flexibility.[42,43] DXA-determined muscle mass may be less directly associated with these factors and may be a better proxy measure of overall muscle mass and body composition. Measures of physical performance and/or muscle strength may therefore be more robust predictors of fractures compared with sarcopenia definitions which also include DXA-determined ALM as measures of muscle mass in this population of older women.[21]

Sarcopenia is associated with a higher risk for mortality but varies depending on the definition of sarcopenia used.[44-46] However, in a recent systematic review and meta-analysis including 42,108 individuals aged 18 years and above, irrespective of the definition of sarcopenia used, it was associated with a higher mortality risk.[33] Contrary to the findings of the abovementioned study, sarcopenia defined by SDOC was the only definition associated with a higher mortality risk in this population of Swedish older women. Muscle strength and/ muscle performance therefore appears to be an important marker of mortality risk.[47] In addition, it was evident that the association was considerably stronger for mortality than for fracture risk when all clinical risk factors were considered in this population of older women even when sarcopenia was defined by the SDOC definition. Similarly, in a study including 13,421 community-dwelling men and 4,828 community-dwelling women, both low handgrip strength and gait speed based on the SDOC definition were associated with a higher likelihood

15

of mortality.[36] This finding may be reflective of the current study results suggesting that sarcopenia definitions including handgrip strength and gait speed but not necessarily DXA-determined lean mass are important determinants of mortality risk among older adults.[36]. Although, ALM is not associated with mortality or fracture risk, it may be associated with other adverse health outcomes such as falls.[41] In addition, assessing muscle mass using other modalities such as through creatine dilution, peripheral quantitative computed tomography or high-resolution quantitative computed tomography may be more robustly associated with mortality and fracture risk among older adults.[41,48] Further studies are therefore warranted to assess the value of such indices and to understand the importance of muscle mass as a sarcopenia component and its effects on negative health implications in this population of older women.

This study is subject to limitations including the relatively low number of hip fractures in this population of older women. In addition, all study participants resided in the greater Gothenburg area in Sweden and this study exclusively included women. As such, the results may not be generalized to men and other populations including individuals with different ethnic backgrounds or age groups. Although the 10 meters course used in this study, is one of the most widely used assessments for gait speed, the use of this course instead of the 4-meter course to assess gait speed (as recommended for SDOC) may have influenced the prevalence of sarcopenia in this study.[49] Although an adjustment for the statistical analysis for BMI, clinical risk factors, and aBMD, other potentially important comorbidities were not accounted for which may have affected the results. It is essential to note that the absence of adjustment for these unaccounted comorbidities could introduce biases that may influence both the magnitude and direction of the observed associations. Therefore, it is crucial to interpret the results with caution, acknowledging the potential for residual confounding effects, particularly related to unaccounted comorbidities, and recognizing the need for further research

Downloaded from https://academic.oup.com/jbmr/advance-article/doi/10.1093/jbmr/zjae026/7604448 by University of Southampton user on 18 March 2024

to refine and validate these findings. The current study utilized 30 seconds chair stand test rather than the standard 5 times chair stand test which are part of the EWGSOP2 and AWGS definitions, which may have influenced the prevalence of sarcopenia in this cohort. Due to the low statistical power, we could not compare the overlap between different sarcopenia definitions in this cohort. Hence, analysis from available larger cohorts, for example, the Rotterdam study,[50] with data on sarcopenia and fractures to compare fracture risk between different definitions to better understand the underlying mechanisms could be warranted. Furthermore, the low prevalence of SDOC found in this cohort suggests that incorporating the definition in existing fracture prediction tools will not have a substantial impact on fracture risk in most older women, since a very small proportion is expected to have their fracture risk reclassified if SDOC were to be added. Moreover, applying cut-points developed in Asian populations (AWGS) to the current study cohort may introduce uncertainties and it is important to interpret the results with caution, as the muscle mass and strength profiles of our population may differ from those in the Asian population for which AWGS was originally designed.

In conclusion, the SDOC definition was the only investigated sarcopenia definition associated with fracture risk. Further studies are required to determine if sarcopenia components should be an integral part of fracture prediction tools to reduce the overall burden of adverse health outcomes in this population of older women.
