Abstract

Background: As certain medications increase risk of falls, it is important to review and optimise prescribing in those who have fallen to reduce risk of recurrent falls.

Objectives: To systematically review evidence on the prevalence and types of potentially inappropriate prescribing (PIP), including falls-risk increasing drug (FRID) use, in fallers.

Methods: A systematic search was conducted in July 2024 in MEDLINE, EMBASE, CINAHL, and Google Scholar using keywords for fall events, inappropriate prescribing, and FRIDs. Observational studies (cohort, case-control, cross-sectional, before-after) and randomised trials were included. Studies were eligible where participants had experienced a fall and PIP (including FRID use) was reported. Random-effects meta-analyses were conducted to pool prevalence of inappropriate prescribing and mean number of inappropriate prescriptions across studies, with stratified analysis to assess heterogeneity.

Results: Fifty papers reporting 46 studies met the inclusion criteria. All studies assessed FRIDs, and twenty-nine assessed other PIP. The prevalence of PIP at the time of the fall was reported in 43 studies, and the pooled estimate was 68.6% (95%CI 66.1-71.2%). Among 23 studies reporting it, the mean number of inappropriate prescriptions per participant was 2.21 (95%CI 1.98-2.45). The most common FRIDs prescribed were sedatives/hypnotics, opioids, diuretics, and antidepressants. Twenty-one studies assessed changes in PIP prevalence post-fall; nine reported decreasing prevalence, with others noting increases/no change/mixed results.

Conclusion: Inappropriate prescribing is highly prevalent among fallers, with cardiovascular and psychotropic drugs being the most common. This suggests significant scope to optimise medicines use in these patients to potentially reduce falls risk and improve outcomes.

Introduction

Medication-related harm is a growing concern and international priority in improving patient safety.(1) Falls are a common adverse outcome which may have medication-related contributors,(2-4) and are often recurrent. Falls can have a significant and often profound impact on people who experience them, such as reduced mobility or independence, premature admission into long-term care, and negative impacts on mental health.(5-7) A fall may present an important opportunity to optimise medication, address potentially inappropriate prescribing or PIP (i.e. posing more risks than benefits for a patient), and reduce the risk of future falls and fractures, or other medication-related adverse outcomes.(8, 9) As falls are multifactorial, current guidelines recommend that medicines review forms part of multi-faceted interventions to reduce falls risk.(10) Adverse events such as falls can prompt reactive medicines review and deprescribing, which occur less frequently in the absence of such triggering events.(11)

Understanding the scope for medicines optimisation among fallers is important to inform targeting of interventions, including which types of drugs are most often implicated in PIP for this group. A previous systematic review quantified the use of falls-risk increasing drugs (FRIDs) among older adults with a fall-related injury and identified 14 studies where prevalence exceeded 65% and no reduction in prevalence was seen after a healthcare encounter.(12) However, this review did not consider other non-injurious falls, nor examine other aspects of potentially inappropriate prescribing, not relevant to falls, and where broader medicines optimisation could be targeted among fallers to improve patient outcomes.

Therefore, the overall aim of this systematic review is to investigate the prevalence of PIP (including the use of FRIDs) in people with a fall or fall-related injury/event. A secondary aim is to determine the types of drugs most often implicated, and whether the prevalence of PIP changes after a fall.

Methods

This systematic review was pre-registered on PROSPERO (CRD42023417534), conducted in line with JBI guidance,(13) and is reported according to the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) statement.(14)

Eligibility criteria

The following eligibility criteria were applied:

Study type: We included observational studies (cohort, before-after, case-control, cross sectional), and randomised trials where the population studied were people who had fallen. Systematic reviews were excluded however any relevant reviews were examined for potentially eligible studies. Other publication types (e.g. conference abstracts, study protocols, commentaries, case series) were excluded.

Population: We included studies focusing on adults of any age who experienced a fall (based on any definition). Fall-related events such as fracture and syncope were also included. Studies in which the sample population was people attending a falls clinic or similar were included where 70% or above of study participants had a fall or a fracture or where less than 70% of participants had a fall or fracture but characteristics of fallers such as age, sex and prevalence of PIP were reported. For case-control studies, only those studies with falls as an outcome that assessed medication exposure within 90 days prior to the fall (indicating likely medication use at the time of fall) were included. Studies were excluded where people who had fallen were an incidental subgroup of the main study population, and not part of the study inclusion criteria.

Outcome: We included studies reporting prevalence of PIP, defined using any approach (e.g. validated tools, lists of medication, specific criteria or indicators, local definitions or where medication use was implicitly judged to be inappropriate). This included any FRID use (as continuing FRIDs in fallers was considered potentially inappropriate), other inappropriate prescribing that is deemed to be relevant to fallers (e.g. anticoagulant use due to increased likelihood of bleeding with recurrent falls, omission of bone protection treatment) and any inappropriate prescribing unrelated to falls (including inappropriate omissions). Studies that assessed inappropriate prescribing of only single drugs/drug classes were excluded.

Information sources and search strategy

MEDLINE (ovid), EMBASE, CINAHL and Google scholar (via Harzing's Publish or Perish)(15) were searched from inception up to the search date of 5th July 2024. The search strategy (included in supplementary tables 1-4) was developed using a combination of subject headings, keywords and synonyms relating to PIP or FRIDs and falls or fractures. No language or other restrictions were used. Any results which were in a different language were translated using online translation software Deepl (www.deepl.com). Grey literature sources were not searched, as given the subject it was anticipated that such sources would be unlikely to contribute significantly.

Selection process

Results from each database were combined, and one reviewer deduplicated using Endnote. Remaining results were uploaded to Rayyan, and its deduplication function was used. Pilot title and abstract screening was conducted on 50 records in Rayyan to ensure the eligibility criteria were applied consistently by all reviewers. Following this, each title and abstract was screened independently by two reviewers (of TOR, LB, JGL, FM). Any disagreements were discussed to reach consensus, or failing this, a third independent reviewer (of CMcA, FM, TOR) assessed the study. A similar process was followed for full-texts, with a pilot on three studies followed by independent review in duplicate, with disagreements resolved as before.

Data Extraction and Data Items

A Microsoft Excel sheet was developed to extract data and piloted using three studies. Data was extracted by two independent reviewers (of TOR, LB, JGL). Once complete, a third reviewer (FM) checked data for consistency and accuracy across reviewers and studies. Data was extracted on:

- **Study Information:** Design, sample size, time frame, geographical location, setting, duration of follow up.
- **Participant information:** Demographics, definition of falls used, proportion with fall/fracture or where reported, proportion of distinct types of falls/fractures.
- **Outcome information:** definitions of PIP (including FRID use categorised as psychotropic, cardiovascular, and other classes), (2-4) time frame prevalence was measured over, prevalence of PIP, prevalence of specific drug classes (involved in PIP/FRID use), and any change in prevalence post-fall.

Outcomes

The primary outcome measure was prevalence or mean number of PIP among fallers. For studies reporting prevalence at multiple time points, the time point closest to the fall was recorded, likely reflecting the medications being taken at the time of the fall. For before-and-after studies and randomised trials, if the prevalence of inappropriate prescribing was reported after a fall, unless explicitly stated that no medication changes had occurred, the prevalence at the latest pre-fall time point was recorded. The change in prevalence of PIP at later time points post-fall, where reported, was extracted as a secondary outcome.

Quality assessment

Study quality was evaluated using the JBI Prevalence Critical Appraisal tool.(16) This assessment was conducted independently by two reviewers (of TOR, LB, JGL) during the data extraction process.

Data Analysis

Characteristics of included studies were summarised descriptively. Meta-analysis of prevalence estimates, and mean number of PIP was performed using the *metan* package in Stata.(17) Heterogeneity can be a concern in meta-analysis of prevalence; the I^2 statistic and Cochran's Q test are reported despite limitations,(18) and this was supplemented by stratifying analyses by study characteristics (i.e. setting, inclusion of fractures, time frame for prevalence measurement, and PIP definition).

Results

From 3,909 records identified, after deduplication 2,789 titles/abstracts were screened, and 164 publications underwent full-text review (see Figure 1).(19) Overall, 50 publications, relating to 46 studies, met the eligibility criteria. Two studies reported relevant results in two publications each, (20-23) while another study had its results published across three different publications.(24-26)

Quality assessment

Included studies were mostly of high quality (supplementary table 5), however twenty studies had small sample sizes ($n < 200$), while nine studies did not describe the study setting in detail.

<insert Figure 1 here>

Figure 1 PROSPERO flow diagram of included/excluded publications.

Study characteristics

Of the 46 studies published between 2007 and 2024 (Table 1), nineteen were cohort studies, eleven were cross-sectional studies, ten were case-control studies, four were before-and-after studies, one was a quasi-experimental study, and one was a randomised controlled trial. Studies were performed in the USA ($n=9$, one conducted in the USA/Mexico border region), Japan ($n=5$), Sweden ($n=4$), France ($n=3$), United Kingdom ($n=3$), Australia ($n=2$), Czech Republic ($n=2$), Ireland ($n=2$), Netherlands ($n=2$), Taiwan ($n=2$), with one study each from Austria, Belgium, Brazil, Canada, Colombia, Denmark, Finland, Germany, Malaysia, New Zealand, Norway, and Spain.

The most common age restriction was ≥ 65 years ($n=26$); all but six studies required participants to be ≥ 50 years. Two studies had no age restriction,(27, 28) although one of these included geriatric day hospital patients, and four required patients to be adults (aged $\geq 18/\geq 20$ years).(29-32) Mean or median age of participants was ≥ 65 years in all studies, and was ≥ 80 years in thirty-three studies, while females accounted for most fallers in all studies except five (where between 53.9% and 62.1% of fallers were male).

Twenty-three studies included participants with falls or fall events, twenty studies focused on fractures, while two studies focused on falls and syncope,(30, 33) and one on falls, fractures and syncope.(34) Falls and fractures were defined in different ways across the studies. Twenty-two studies described fall events using different free-text definitions which were developed with reference to literature. Twelve studies defined falls/fractures using International Classification of Diseases (ICD) codes.(35) Nine studies did not report how falls/fractures were defined. One study used the AO/OTA fracture and dislocation classification compendium to define a fracture.(36) One study used the visual SQ method to define vertebral fractures as proposed by Genant et al.(37, 38) One study used the French Society of Geriatrics and Gerontology criteria for serious falls.(28)

Thirty-three studies included inpatients and/or attendees at emergency departments, six studies included attendees of an outpatient clinic, five studies included community-dwelling individuals with a record of a fall across inpatient and outpatient/ambulatory care settings (or unspecified settings), and one study each included individuals from a retirement facility,(39) and from both a nursing home and hospital geriatric care unit.(40)

Numbers of participants ranged from 29 to 1,678,037. In 34 studies, 100% of their participants had a fall, one study of 200 consecutive hip fracture patients identified that 98.5% of participants had a fall (41), while another study in a geriatric day hospital included 82% of participants with a recent fall history.(28) In the ten case-control studies, the percentage of fallers included in the study ranged from 6.6% to 73.8%.

Definitions of PIP

In assessing potentially inappropriate prescribing among fallers, all studies considered FRIDs (in some cases as part of a validated tool for PIP). Three studies assessed only a single category of FRIDs (psychotropics), four studies assessed two categories of FRIDs (three studies assessed psychotropic and other categories, and one study assessed psychotropic and cardiovascular categories), while the remaining thirty-nine studies assessed all three categories. Overall, 46, 42 and 40 studies assessed psychotropic, other, and cardiovascular FRIDs respectively. Twenty-nine studies also assessed other forms of PIP, of which twenty-eight assessed PIP relevant to falls, and fourteen studies assessed non-fall relevant PIP.

Thirty-six studies cited literature source(s) for their PIP definition (including FRIDs), seven cited literature source(s) and expert opinion, two studies referred to expert opinion/review alone, and one did not state the source. Twenty-six studies reported the use of a validated tool for defining PIP. Seventeen studies used a single tool, most often the Beers criteria (five studies) or the STOPP criteria (six studies), and one study each used the STOPPFall criteria, Drug Burden Index, Anticholinergic Cognitive Burden score, Anticholinergic Drug Scale, the Salahudeen extended Anticholinergic Rating Scale, and the Swedish National Board of Health and Welfare indicators. Eleven studies used combinations of tools, most often STOPP/START (n=3), with one study each using other combinations of tools (STOPP/START and Beers criteria, STOPP/START and the PRISCUS list, STOPP/START and Sweden's FRID list, STOPP/START and Medication Appropriateness Index, STOPP and Beers, START and Beers, Beers and Lexi-Interact®, and Beers and the STEADI-Rx list).

Thirty-six studies assessed prevalence of PIP at a time point, most often reported as at admission (twenty-five studies) followed by at the time of or on the day of the fall

(seven studies), while ten studies assessed PIP prevalence over a time period, ranging from three days to twelve months pre-fall.

Table 1. Descriptive characteristics of included studies, listed by year of publication

Study, year, location	Study design, setting, time frame	Fall-related inclusion (% with event), sample size	Source of PIP definition (specific tool used)	PIP definition categories					Time frame of PIP prevalence measurement
				FRID CVD	FRID Psy	FRID Oth	PIP Fall	PIP Oth	
van der Velde et al. 2007 (42) Rotterdam, Netherlands	Prospective cohort study, Geriatric Outpatient Clinic, ≥65 years 19 months, Apr 2003 - Nov 2004	Fall (100%) n=139	Literature source(s)	Yes	Yes	Yes	No	No	Time point, Admission to Geriatric Outpatient Department

Overall prevalence of PIP

A measure of the prevalence of PIP was reported by all included studies, with the percentage of participants with PIP reported in forty-three studies, and the mean number of PIP occurrences per participant was reported or calculable in twenty-three studies (table 1). Twenty studies reported both measures.

The prevalence ranged from 15% to 99%. Across 317,914 participants in included studies, the pooled prevalence (Figure 2) was estimated at 68.6% (95%CI 66.1%, 71.2%), however there was substantial between-study heterogeneity (I^2 99.5%, Cochran's Q $p < 0.001$). Heterogeneity was examined in sub-group analysis, and this was not explained by any aspect of study design or included participant characteristics (see supplementary table 6).

<insert Figure 2 here>

Figure 2. Forest plot for random-effects meta-analysis of studies reporting prevalence of potentially inappropriate prescribing

In the twenty-three studies reporting the mean number of PIP occurrences per participant, this ranged from 0.6 to 5.1. Overall two studies reported means less than 1, nine between 1 and 2, five between 2 and 3, and seven between 3 and 4. The pooled mean (Figure 3) was estimated at 2.21 (95%CI 1.98, 2.45) PIP occurrences per participant, however there was substantial between-study heterogeneity (I^2 99.5%, Cochran's Q $p < 0.001$). Overall prevalence was not explained by study design or included participant characteristics, with the exception of whether PIP was assessed at a time point (mean 2.12, 95%CI 1.65, 2.68) or over a period (mean 2.77, 95%CI 2.38, 3.16), $p = 0.034$ for Cochran's Q statistic for between-group heterogeneity (see supplementary table 7).

<insert Figure 3 here>

Figure 3. Forest plot for random-effects meta-analysis of studies reporting mean number of potentially inappropriate prescribing occurrences per participant

Prevalence of individual PIP drugs

Thirty-five studies reported on the prevalence of different drug classes implicated in PIP, and up to the top five most prevalent are reported in Figure 4. Sedative/hypnotic drugs and opioids were reported in 13 studies each, with the percentage of participants prescribed them in the ranges of 3.6-36.5% and 8%-38.1% respectively. The next most frequently reported in twelve studies each were antidepressants (7.5%-56%) and diuretics (12%-60.4%).

<insert Figure 4 here>

Figure 4. Heat plot of the prevalence of the top 5 drug classes reported as involved in potentially inappropriate prescribing (including falls-risk increasing drugs)

Note: Drug classes only reported among the top 5 classes in fewer than two studies were omitted.

Changes in PIP prescribing

Twenty-one studies examined change in prevalence of PIP after the fall (supplementary table 8), with eleven of these measuring changes in prevalence at discharge (and two of these also followed up at six and twelve months). The remaining ten measured changes in prevalence over the following one, three, four, six and/or twelve months. An increase in PIP post-fall was identified in five studies.(24, 34, 44, 55, 62) Three studies identified no change, while a further five identified mixed results (i.e. increases, decreases, and/or no change across different drug classes or follow-up periods). The remaining nine studies identified reductions in PIP post-fall.

Discussion

Overall, this systematic review of 46 studies identified that PIP is common among fallers internationally. Most studies involved ED/hospitalised patients 65 years and over, all evaluated FRID use while approximately two-thirds also assessed other forms of PIP. The pooled PIP prevalence was 68.6%, with fallers having 2.2 PIP occurrences on average. The most commonly reported drug classes were opioids, sedatives/hypnotics, antidepressants, and diuretics. Fewer than half of studies (n=21) evaluated change in PIP over time, and just under half of these found a reduction in PIP post fall. Few studies examined non-falls-related PIP, which makes it challenging to compare the most prevalent types of PIP among fallers with previous research in general populations, and suggests a need for further research.

Opioids, sedatives/hypnotics, antidepressants, and diuretics were the medication classes most frequently reported as falls-risk increasing or potentially inappropriate in fallers, corresponding to the three major categories of FRIDs. Diuretics have been shown in the literature to be a leading cause of medication-induced orthostatic hypotension and volume depletion in older patients,(72) which may explain their high prevalence among fallers. Opioids can cause sedation and cognitive impairment, with pharmacokinetic changes in older adults amplifying these effects and increasing falls risk.(73) Sedative and hypnotic medications such as benzodiazepines are among the most prescribed psychotropic medication, and particularly with chronic use leading to dependence and tolerance, they can cause sedation, impaired balance and potentially cognitive impairment, all risk factors for falls.(74) The broad clinical domains of these medications underlines the importance of a holistic assessment of prescribing appropriateness among fallers, especially those with multiple chronic conditions.

Deprescribing long-term medications can be difficult and may explain why medications deemed to be potentially inappropriate may be continued. Various deprescribing guidelines are available, including for benzodiazepines and opioids,(75, 76) while a diuretics guideline is in development.(77) These provide evidence-based recommendations to support decision-making, covering how to identify when and how to reduce or stop medications which are no longer necessary or where potential risks outweigh benefits. An adverse event such as a fall may provide strong support to consider deprescribing, weighed against potentially beneficial effects of the medication.(78) It may be clinically appropriate to continue some potentially inappropriate prescriptions after a fall where the long-term benefits outweigh the anticipated harms, and so some level of post-fall FRID use may be appropriate. Evidence to date on the effect of deprescribing interventions for falls prevention has been mixed,(79, 80) and further robust evaluations of the impact of such interventions as part of multifactorial strategies among patients with falls would be beneficial.

Notably there was substantial between-study heterogeneity both in the proportion of people with falls who had PIP, and mean PIP occurrences. For mean PIP occurrences, this was partly explained by whether PIP was measured at a time period or over a period, indicating a time point may not capture the full complexity of medication use.(81) However, substantial heterogeneity remained among studies, and this could not be explained by reported study-level characteristics. Studies used a variety of different definitions for PIP and reported these differently (e.g. total prevalence or prevalence per validated tool). Even among studies using the same tool, such as STOPP/START or Beers criteria, different versions of these or adaptations to the local context (e.g. due to lacking the data required for application or medications not available in a jurisdiction) may contribute to heterogeneity in prevalence estimates. Future studies should ensure that any such adaptations are clearly reported as some studies did not clearly describe which criteria were applied or omitted. Considering that there are a multitude of factors that contribute to PIP, it is likely that other characteristics not measured or reported at both study- and participant-level e.g. prevalence of particular conditions or number of medicines, may further explain heterogeneity.

Strengths and limitations

A strength of this review is the inclusive approach for defining falls and related-events, populations and settings, and potentially inappropriate prescribing, yielding a comprehensive synthesis of research in this area, which complements other more focused evidence synthesis such as the review of falls-related injuries, which included only 14 studies, all of which were included in this review.(12) The review protocol was pre-registered and followed methodological guidance for systematic reviews of prevalence studies. Limitations include the focus on peer-reviewed literature, given the likely low contribution of grey literature sources to the topic, however potentially relevant research may be omitted. Heterogeneity in prevalence was high, which may reflect differences in study design, populations, drug classes used to define PIP/FRIDs and other aspects not examined in stratified analyses.(18) Within the review timeframe, it was not feasible to contact study authors to obtain information not reported. For example heterogeneity in how drug and drug class prevalence was reported across studies impeded further statistical analysis for specific drugs/classes.

Implications

Future studies on this topic should adopt a standardised approach to recording and reporting medication use at the individual drug and drug class levels, which would enhance the evidence base for targeted approaches to address FRIDs among fallers. Similarly, more comprehensive assessment of not just FRIDs, but also other forms of PIP among fallers should be considered in further research, including a full description of the criteria applied. Further research is also needed to determine the

extent to which medication review and optimisation occurs after a fall, as fewer than half of included studies reported on this.

Depending on the healthcare context, a falls admission may provide an opportunity to review and optimise medicines use in general, for example, where a fall-related admission triggers a comprehensive geriatric assessment. The recent World Guidelines for Fall Prevention and Management recommend medication review and appropriate deprescribing of FRIDs as part of multifactorial falls prevention.(10) However a recent systematic review on the effectiveness of medication review and deprescribing interventions as a single intervention in falls prevention identified wide heterogeneity in interventions and did not identify a significant effect, (although this was among all populations, not specifically people with an existing fall).(80) Likelihood of benefit may be increased by focusing on individuals taking FRIDs with strong evidence of an impact on falls or other factors which predict falls risk.(82, 83)

Conclusion

The high prevalence among fallers of potentially inappropriate prescribing, including FRID use, identified in this review suggests significant scope for medicines optimisation in this group. This could focus on falls risk reduction and improving prescribing appropriateness more generally, however the evidence that this occurs routinely is limited and mixed. Improved targeting of deprescribing interventions to address key FRID classes, as part of multifactorial falls prevention strategies may ultimately reduce future falls and improve patient outcomes.

Identification

Records identified from:
 Databases (n = 3,909):
 Medline (ovid) (n = 1,105)
 Embase (n = 1,946)
 CINAHL (n = 658)
 Google Scholar (n = 200)

Records removed before screening:
 Duplicate records (n = 1,120)

Records screened
 (n = 2,789)

Records excluded
 (n = 0)

Reports sought for retrieval
 (n = 169)

Reports not retrieved
 (n = 5)

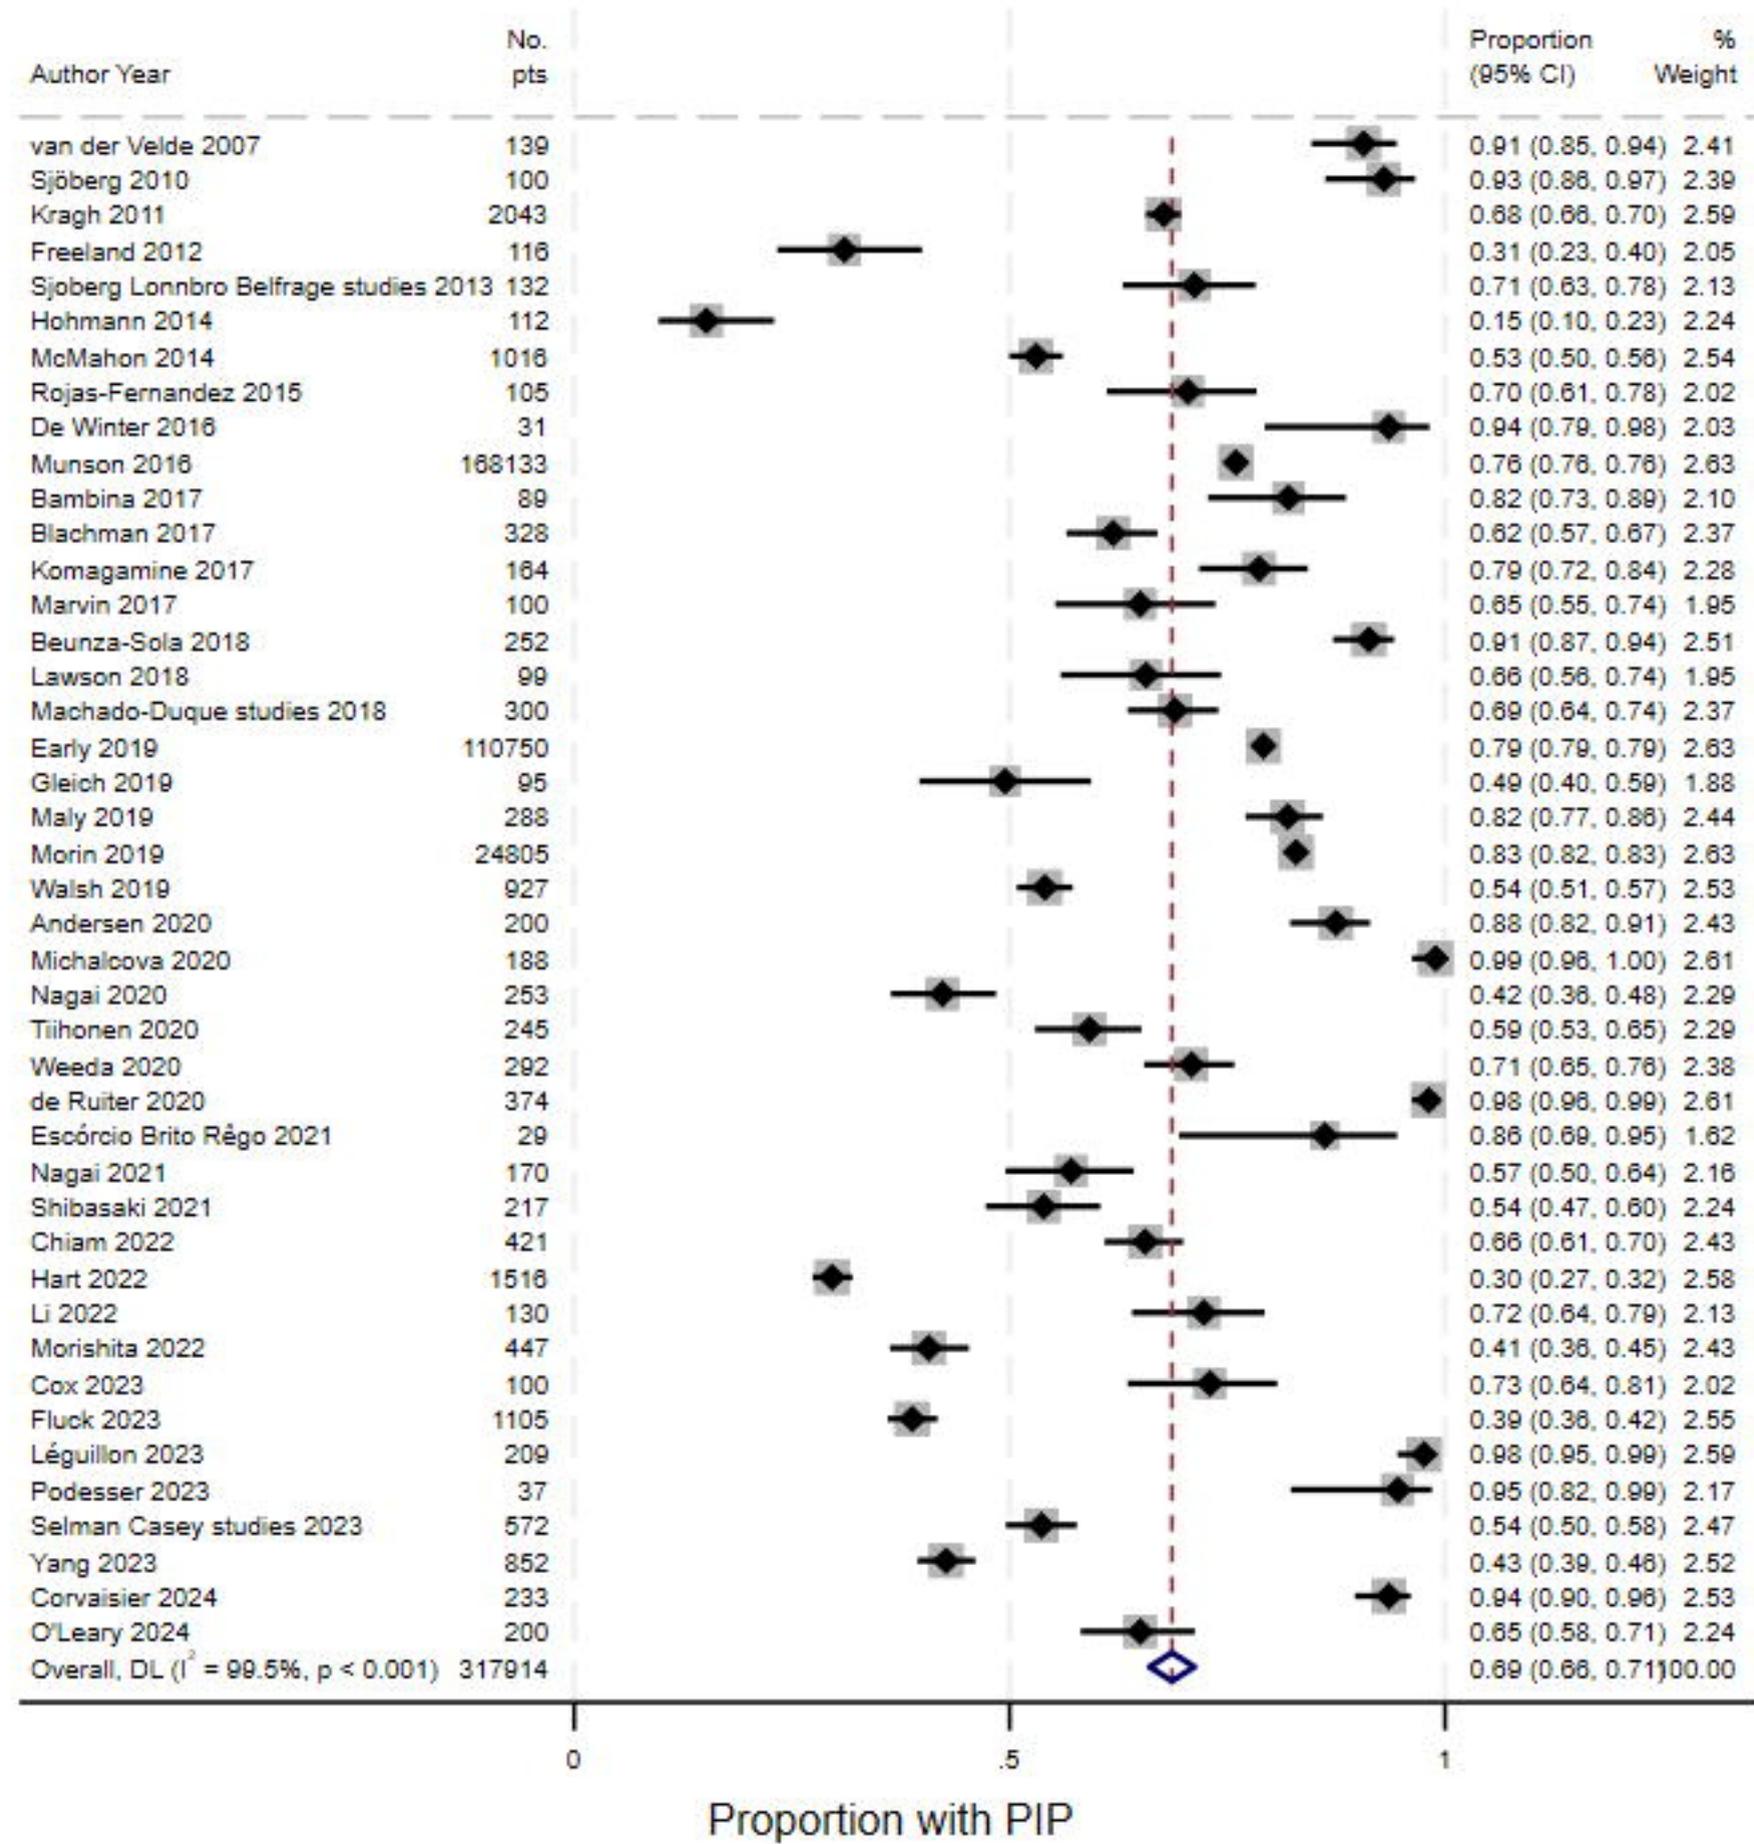

Screening

Reports assessed for eligibility
 (n = 164)

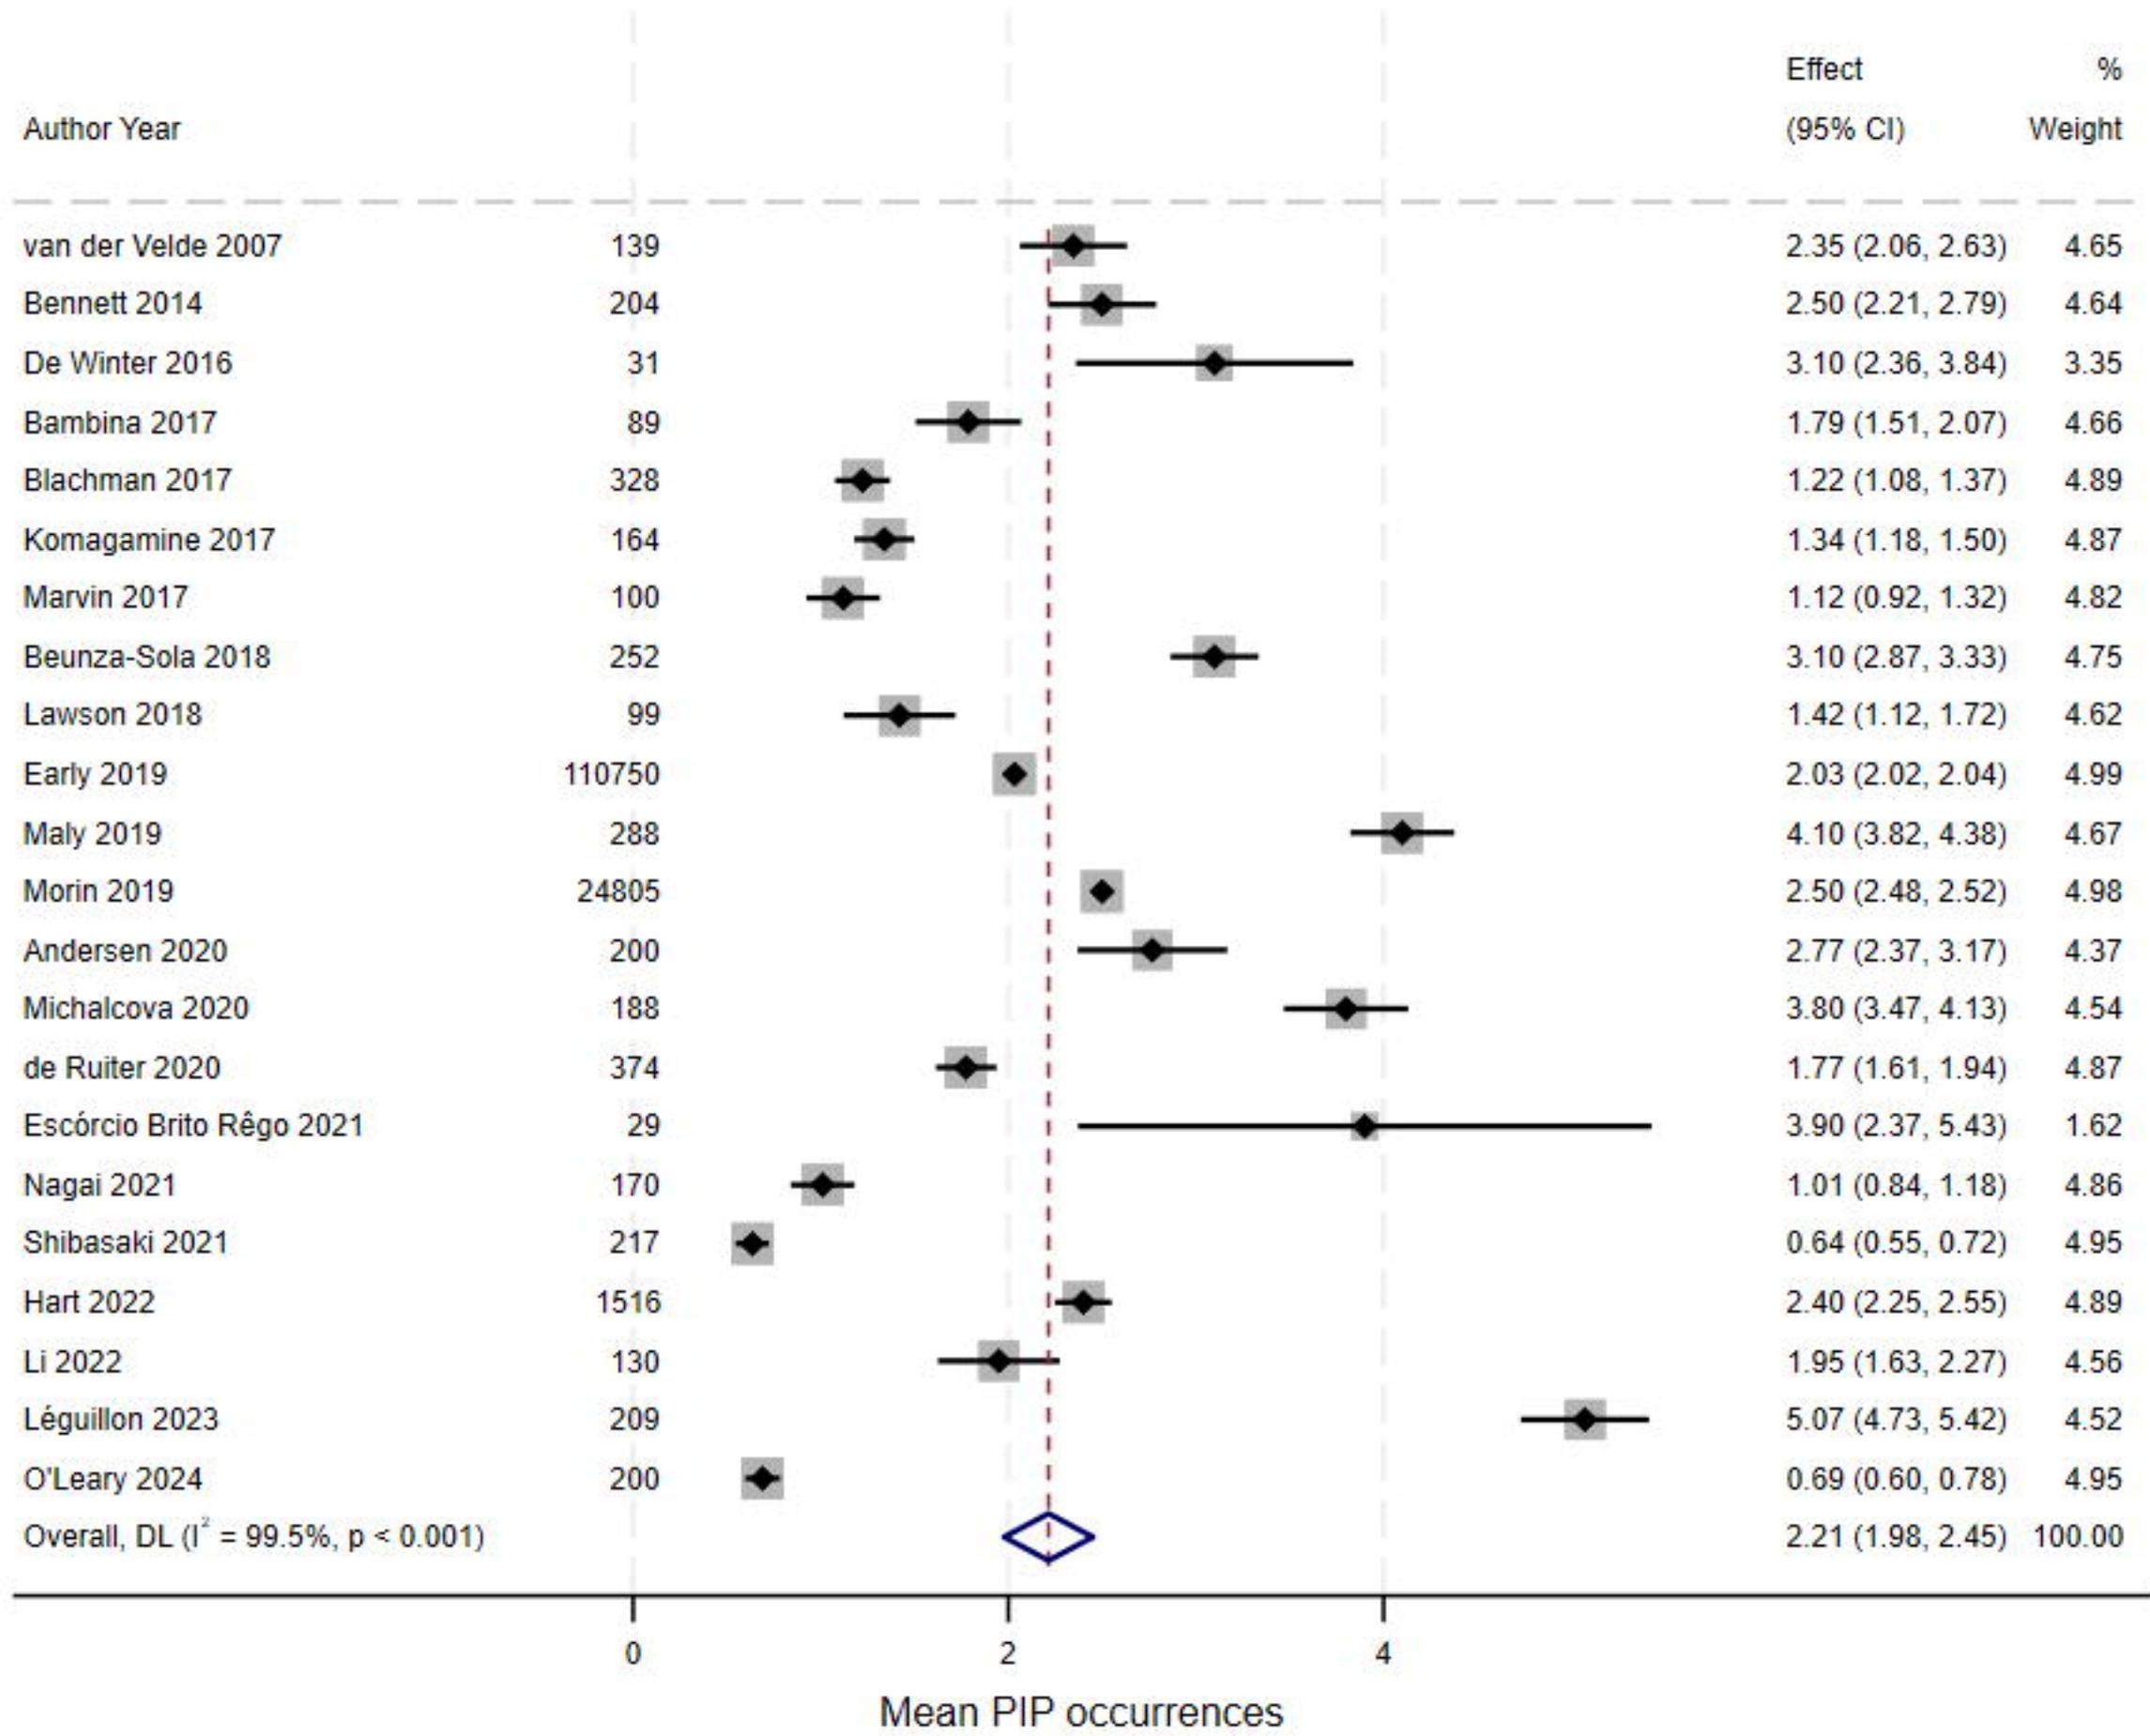

Reports excluded:
 Study population not fallers (e.g. falls as outcome) (n = 23)
 No prevalence of PIP/FRIDs (n = 7)
 Single PIP/FRID drug or drug class (n = 3)
 Medication assessed after fall only (n = 9)
 Medication assessed >3 months before or after fall (n = 3)
 Eligibility criteria included >1 FRID (n = 3)
 Conference abstract (n = 60)
 Review/commentary (n = 4)
 Thesis (n = 2)

Studies included in review
 (n = 46)
 Reports of included studies
 (n = 50)

Included

NOTE: Weights are from random-effects model; continuity correction applied to studies with zero cells
